## Section 1: Purpose of the Study

Traditional life experience studies show actual claims as a ratio of a reference table. Various splits of the experience show familiar relationships, illustrate new insights, and allow benchmarks. Despite traditional studies' advantages, actuaries are familiar with a disadvantage: distortions due to different mixes of business between segments within the study, and between the study and an actuary's own book of business. Ratios to the reference table can be raised or lowered due to the inclusion of another business segment and therefore make for poor adjustment factors.

Despite the issue that mixing heterogeneous segments can distort results, segments are typically aggregated to gain a larger volume of experience. This paper demonstrates an approach to addressing the issue by modeling experience, and then interpreting the model and residual errors instead of actual / table ratios alone. Appendix $G$ of the 2017 ILEC report (select mortality by age, plan, and duration) is taken as an example, modelling on more attributes than the splits shown in the report. Two types of models are presented: generalized linear models (GLM), and a regression tree.

The GLM, in practical terms, determines the 2015 VBT adjustment factors for various splits of business in order to match the total experience corresponding to each factor simultaneously. For example, adjustment factors for each face amount band, underwriting class, etc. are calculated in tandem, so the total adjusted mortality within each specific face band, underwriting class, and other adjusted category is $100 \%$. The adjustment factors are then compared to the actual / table ratios to find anomalies. More formally, the GLM used here uses a log link with an offset, i.e. item that is adjusted, of the expected claims under the 2015 VBT. The splits chosen are those for which actual / table ratios are typically presented. These models are less susceptible to being skewed by different mixes of business. There is a disadvantage: a large adjustment to the underlying expected in a cell could imply an underlying mortality rate over 100\%. For examining experience, however, this disadvantage is heavily outweighed by the advantage of communicability of the factors, and comparability to the more familiar actual / table presentation of experience. The adjustment factors are also volatile for thin cells. The experience is quite heterogeneous as is clear from the ranges of issue and study years. The two GLMs fit policy count and face amount on splits of the following characteristics:

1. issue year (iy_band1): -1989, 1990-1999, 2000-2009, 2010-. There is little experience through 1989, as experience is durations 1-25 and the study period is 2009-13.
2. underwriting class (class_key): showing whether SM/NS, number of underwriting classes, and which underwriting class: Nonsmoker 2 1, Smoker 2 1, etc.
3. insurance_plan: Other, Perm, Term, UL, ULSG, VL, VLSG
4. level term period (ltp): the anticipated level term period. 20-year term and "N/A (Not Term") are combined in this field as "20 yr or N/A (Not Term)" because the insurance plan field already distinguishes between term and other plans. Without combining the 20-year term indicator and the "not term" indicator we would have two indicators whether the business is term, in the level term period field and in the plan field. Note that much of the source term data has "unknown" level term period.
5. issue age band (ia_band1): generally quinquennial bands
6. duration band (dur_band1): $01,02,03,04-05,06-10,11-15,16-20,21-25$
7. observation_year: 2009, 2010, 2011, 2012, and 2013 individually, each with a factor
8. gender: Female, Male
9. face_amount_band: 1-9999, 10000-24999, etc. The low face business is of questionable quality. It may include insurance which has not been fully underwritten.

Some of these characteristics will be correlated. Issue year ranges in iy_band1 will overlap the study period in different duration bands, for example. Face amounts and products issued as well as underwriting structures have changed over time, and will only be observed in some durations. The correlations between the explanatory variables are an important topic to address when developing a model to be used for prediction, and is intentionally not covered in this description of experience. This paper is not a solution to those problems, but a supplemental way to examine and analyze the experience.

A second type of model was used for describing these results. A tree approach was applied to the observed actual/table ratios, so as to split the data into more homogeneous groups, as measured by their relative actual/table factors. Technically, the rpart routine of R was used, with each record's actual/table ratio as the dependent variable, and the same dependent variables as in the regression model. After the tree was build, the average actual/table from the applicable leaf was assigned to each record as an adjustment factor. Conceptually, this is not that different from a regression: we are essentially assigning an average value of similar records to represent the single value of the observed actual/table. This is not unlike a regression fit where the model value is a best fit by averaging similar data to the specific data point in question.

Note that this paper is not a recommendation of a model of industry experience for prediction. The intent is to supplement current experience reporting. A model intended to fit the experience would be considerably more complex, as it would need to fit various cross combinations of business that are not reflected in the models in this paper. The number of possible cross combinations grows quickly with the number of variables modelled. A model for predicting should also be tested against un-modeled data.

## Section 2: Acknowledgements and Resources

### 2.1 Individual Life Experience Committee

The SOA extends its gratitude to the Individual Life Experience Committee (ILEC). The ILEC designed the project, completed/oversaw the analyses and authored and peer reviewed the report. The ILEC members are:

- Tony R. Phipps (Chair), FSA, MAAA
- Edward Hui (Vice-Chair), FSA
- Mary J. Bahna-Nolan, FSA, MAAA, CERA
- Tatiana Berezin, FSA, MAAA
- Kathryn A. Campbell, FSA, MAAA
- Christopher M. Condon, FSA, MAAA
- Jeffery T. Dukes, FSA, MAAA
- Roland Fawthrop, FSA, MAAA
- Dieter S. Gaubatz, FSA, FCIA, MAAA
- Brian D. Holland, FSA, MAAA
- Douglas A. Ingle, Underwriter
- Kevin P. Larsen, ASA, MAAA
- Hezhong (Mark) Ma, FSA, MAAA
- Stephen J. MacDonald, Underwriter
- Nikolai D. Serykh, FSA, FCIA
- Maureen A. Shaughnessy, FSA, MAAA
- Frans W. Te Groen, FSA, MAAA

### 2.2 Other Resources

The SOA contracted with MIB's Actuarial and Statistical Research Group, to collect, validate, and compile the data for this report. Yara Rodgers-Silva, Principal Statistical Modeling at LexisNexis Risk Solutions, helped with the review and discussion of the contents of the report. Mervyn Kopinsky, FSA, EA, SOA Experience Studies Actuary, provided assistance with some of the modeling work, and Erika Schulty, SOA Research Associate, helped coordinate and draft the report.

## Section 3: Findings

The most striking results from the GLMs are modeling factors which go in a different direction from the actual / table ratio. One such example is the actual / table for Permanent vs Term. By count, Permanent is $121 \%$ of 2015 VBT vs. $105 \%$ for Term, which would seem to imply that Perm has higher mortality. The Term factor, however, is higher than Perm, so the opposite. To tell why, we can compare the other components of the actual / table ratio between these segments, the average factors for the other categories to find the category with the most differentiation in average factors (Table 1). The average factors for the other categories show that the mix of business within the face amount band is driving the appearance that Perm is higher than Term. Perm is skewed to lower bands, which have higher factors (Figure 1). The ILEC understands that the low bands might include business reported inconsistently by different companies for administrative reasons, which could explain both their presence in a fully underwritten study and the higher mortality allocated to the lower bands by the model.

Table 1: Analysis of A/VBT15 for Permanent and Term

|  | insurance_plan | Perm | Term |
| :--- | :--- | ---: | ---: |
|  |  |  |  |
| A/VBT15 | Observed | 1.21 | 1.05 |
|  | Approximated | 1.22 | 1.05 |
|  | insurance_plan | 0.93 | 1.00 |
|  | Overall | 0.93 | 0.93 |
|  | class_key | 1.24 | 1.04 |
|  | dur_band1 | 0.85 | 0.99 |
|  | face_amount_band | 1.36 | 0.99 |
|  | gender | 1.05 | 1.07 |
|  | ia_band1 | 0.86 | 0.93 |
|  | iy_band1 | 1.02 | 1.04 |
|  | ltp | 1.00 | 1.01 |
|  | observation_year | 1.07 | 1.07 |

Appendix 2 shows a similar exhibit for each characteristic for which the count and the amount models have a separate factor. The example in Table 1 above is one of the more noteworthy examples, because the actual / VBT2015 ratio and the insurance plan factor move so strongly in opposite directions between Term and Perm.

Figure 1: Distribution of 2015 VBT Expecteds (Count) by Face: Term and Perm vs Durational Factor

Model factors alone show potentially misleading relationships in several cases.

- Insurance plans: the factors show the opposite relationship from the actual/table ratios between permanent and term plans.
- Issue ages: the factors show a declining adjustment to 2015VBT, while the actual / VBT ratio is more constant.
- Durations: the factors show a falling relationship versus 2015VBT, while the actual / VBT ratio turns upward after the duration 6-10 band.
- Face amounts: lower face amount bands have a higher adjustment factor than the actual / VBT ratio alone would indicate.
- Issue years: the actual/2015VBT ratio is high for the latest issue cohort. The model attributes that elevated mortality to the low duration band, which has a higher factor.

Exhibits for all of the factors follow below in Appendix 1, showing A/2015VBT compared to the factors, showing the corresponding approximation of the $\mathrm{A} / 2015 \mathrm{VBT}$ ratio as the product of the average factors.

Note that the low face amount bands heavily skew results by count due data quality concerns already noted.

The low face amount bands also have different durational relationships. These features could be reflected in the model by including adjustments for cross-combinations of different business characteristics. The tree model shows these cross combinations immediately. The full tree is shown in the appendix, and includes the top-level splits shown immediately following. At each node the $\mathrm{A} / 2015 \mathrm{VBT}$ is shown, and the criterion by which the tree is split to go to the next level down. A "yes" or "no" goes left or right as indicated at the top-level node. The first three splits in the tree peel off low band, early duration business (face band minimum < 17500, duration band minimum <3.5) as having a $315.2 \%$ actual / table. Such an exhibit quickly indicates to the subject
matter expert that there could be an irregularity, such as the inclusion of so much business with face below 10,000 that is purportedly fully underwritten. The full model is shown in Figure 22.

Figure 2: Tree model by count: top level splits

As a reminder, 2015VBT as adjusted with any of these models will match the experience in total for any subset for which there is a specific factor. Such a subset is, for example, a face amount band or policy duration band for which there is a factor; or a leaf node of a tree model, which uses the actual / table ratio in that node as a factor. It will not, however, necessarily match the experience at a more granular level within that cell.

### 3.1 Possible Future Directions

Topics which could be covered in future reports are comparisons of further models and modelling techniques:

- Analysis of additional exhibits besides Appendix G from the ILEC report to compare actual / table to adjustment factors
- Calibrating complexity of the model by tuning it against holdback data
- Calibrating the model for prediction of the next year of claims data
- Calibrating the model for variable selection using familiar significance tests
- Use of dimension reduction methods to find and rank interactions of variables

The topics to be explored will depend in part on community interest. Please feel free to express your interest to the ILEC, to the SOA research department, or to me directly.

## Appendix 1: 2017 ILEC Report Exhibit G-Format Model Results

This section shows Exhibit G and also Exhibit G redone using each model instead of 2015VBT.
The GLMs fit $100 \%$ of the experience in total for the edges (plan total, duration band total, face band total) for the metric, face or count, for which they are run. They will not fit within cross combinations of characteristic without the introduction of more complicated factors.

## Appendix 2: Comparisons of Factors and A/2015VBT

This section shows the total actual / 2015VBT compared to the model factor as calculated from the multivariate fit.

Count is used for the count model, $\mathbf{g} \_$count, and amount for the amount model, $\mathbf{g}_{\mathbf{g}}$ amount.

## Appendix 3: Model Formulae

The model formulae are expressed in patsy, an R-style formula specification language. While the syntax is different in other statistical software packages, the logic in the formulae below can be interpreted and translated to other languages.

The dependent variable is specified first, followed by the independent variables. Each independent variable is specified in this case with a $C()$ because they are categorical variables. Each category has one type which is the default against which others are measured, specified as the "treatment" below.

The only difference between the formulae is the dependent variable.
The GLM would be executed as follows, using the statsmodels Python package:
import statsmodels.formula.api as smf
fit $=$ smf.glm( data = data
, formula = "(the formula below)"
, offset = np.log(offset column)
, family = sm.families.Poisson(link=sm.families.links.log)).fit()

Formula for model g_count, using offset column expected_death_qx2015vbt_by_policy:
number_of_deaths ~

+ C(class_key)
+ C(dur_band1, Treatment(reference='06-10'))
+ C(face_amount_band, Treatment(reference=' 100000-249999'))
+ C(ia_band1, Treatment(reference='40-44'))
+ C(gender)
+ C(observation_year)
+C(insurance_plan, Treatment(reference='Term'))
+ C(Itp, Treatment(reference='20 yr or N/A (Not Term)'))
+ C(iy_band1)

Formula for model g_amount, using offset column expected_death_qx2015vbt_by_amount:

```
death_claim_amount ~
    + C(class_key)
    + C(dur_band1, Treatment(reference='06-10'))
    + C(face_amount_band, Treatment(reference=' 100000-249999'))
    + C(ia_band1, Treatment(reference='40-44'))
    + C(gender)
    + C(observation_year)
    + C(insurance_plan, Treatment(reference='Term'))
    + C(Itp, Treatment(reference='20 yr or N/A (Not Term)'))
    + C(iy_band1)
```

The tree model uses the following formula, and was run in R using the rpart package. The maximum depth and complexity parameter cp were chosen for presentation purposes. A model used for prediction should be tuned against holdback data and random forest techniques should be considered. In this case, the tree branches when the variance within a node is sufficiently reduced by some split within that node among the variables given. The variance is the weighted squared error of the observations from the mean when split, compared to the mean when not split. Note that the data are somewhat aggregated before receipt by the ILEC, so variance within the individual records in the source data gets lost.

```
tree_count <- rpart(ae_count ~ preferred_class
    +number_of_preferred_classes +smoker_status +dur_band1_min +face_min
    +ia_band1_min +gender +observation_year +ltp +iy_band1_min
    ,data=data_g
    , maxdepth=8
    ,cp=0.0001
    ,weights=expected_death_qx2015vbt_by_policy)
```

## Appendix 4: Statistical Model Output

The model factors as output by the Python package statsmods include statistical fit metrics as shown below. The columns are:

- The variable for which a factor is calculated. The variable "C(face_amount_band, Treatment(reference=' 100000-249999'))[T. 250000-499999]" is an indicator variable of 1 if the face amount band is 250000-499999, and zero otherwise.
- The natural logarithm of the adjustment factor to be applied to the adjusted metric (expecteds using VBT15)
- The standard error of the coefficient
- The $z$ score: normalizing the coefficient as if it is a normally distributed variant with mean zero and standard deviation of the standard error
- $P>|z|$, the probability that a standard normal would be at least as large as the coefficient
- The $95 \%$ confidence interval of the estimate of the coefficient, calculated as the middle $95 \%$ of a normal distribution with mean of the coefficient and standard error shown.

Model factors are applied by adding up all applicable factors for a given cell of data, and exponentiating the result. Each category has one value which has no adjustment factor and serves as the default category, such as duration band 06-10 for the duration category.

Note that or fits of amount, the statistical descriptors have no meaning.
The model factors fit that category in total. The statistical values such as confidence intervals do not reflect the correlation between amounts. The model effectively counts each dollar of benefit as a separate trial.

This issue is the same issue as having multiple policies on one life, but much more extreme. It is clear from the $z$-scores of the amount model that the correlations between individual dollars are not considered, as they are the equivalent of standard normal variates that come out in the thousands in many cases.

## Figure 22: Tree model by count

Displaying a larger tree can be difficult and less helpful than a smaller tree. One of the challenges of trees is tracing where one variable causes a branch, and in relationship with which other variables. An advantage is that the trees can describe reality more closely than a model with a less flexible structure.

The tree shows the $\mathrm{A} / 2015 \mathrm{VBT}$ by count at each branch. For example, the top node shows the overall $1.155 \mathrm{~A} / 2015 \mathrm{VBT}$ without branching.
Each node in the tree shows a criterion on which the next branch is made, with "yes" to the left and "no" to the right. The top node's criterion is whether the lower bound of the face amount band, face_min, is above or below 75,000 . If not, the tree branches to the right, with a higher (darker) value than for the higher face amount bands to the left.

## About The Society of Actuaries

The Society of Actuaries (SOA), formed in 1949, is one of the largest actuarial professional organizations in the world dedicated to serving 24,000 actuarial members and the public in the United States, Canada and worldwide. In line with the SOA Vision Statement, actuaries act as business leaders who develop and use mathematical models to measure and manage risk in support of financial security for individuals, organizations and the public.

The SOA supports actuaries and advances knowledge through research and education. As part of its work, the SOA seeks to inform public policy development and public understanding through research. The SOA aspires to be a trusted source of objective, data-driven research and analysis with an actuarial perspective for its members, industry, policymakers and the public. This distinct perspective comes from the SOA as an association of actuaries, who have a rigorous formal education and direct experience as practitioners as they perform applied research. The SOA also welcomes the opportunity to partner with other organizations in our work where appropriate.

The SOA has a history of working with public policymakers and regulators in developing historical experience studies and projection techniques as well as individual reports on health care, retirement, and other topics. The SOA's research is intended to aid the work of policymakers and regulators and follow certain core principles:

Objectivity: The SOA's research informs and provides analysis that can be relied upon by other individuals or organizations involved in public policy discussions. The SOA does not take advocacy positions or lobby specific policy proposals.

Quality: The SOA aspires to the highest ethical and quality standards in all of its research and analysis. Our research process is overseen by experienced actuaries and non-actuaries from a range of industry sectors and organizations. A rigorous peer-review process ensures the quality and integrity of our work.

Relevance: The SOA provides timely research on public policy issues. Our research advances actuarial knowledge while providing critical insights on key policy issues, and thereby provides value to stakeholders and decision makers.

Quantification: The SOA leverages the diverse skill sets of actuaries to provide research and findings that are driven by the best available data and methods. Actuaries use detailed modeling to analyze financial risk and provide distinct insight and quantification. Further, actuarial standards require transparency and the disclosure of the assumptions and analytic approach underlying the work.
