## TRANSACTIONS OF SOCIETY OF ACTUARIES

 1981 VOL. 33
## REPORT OF THE COMMITTEE TO RECOMMEND A NEW MORTALITY BASIS FOR INDIVIDUAL ANNUITY VALUATION (DERIVATION OF THE 1983 TABLE $a$ )

## INTRODUCTION

In december, 1979, Mr. Ted Becker, chairman of the NAIC (C4) Life, Accident, and Health Insurance Technical Subcommittee Task Force on Valuation and Nonforfeiture Value Regulation, asked the Society of Actuaries to "form one or more committees to study the possible need for new mortality bases or tables in the following areas: (1) individual and group annuities (mortality and adequacy of improvement projection factors); or settlement options." The Technical Task Force request went on to say: "If it is concluded that one or more additional new bases or tables are needed, then the committee or committees would commence directly with developing new bases or tables just as soon as possible.'’ With the agreement of then President Vogel and then President-Elect Leckie, a committee was formed to study the need for a new individual annuity mortality basis. A corresponding committee was named to examine the need for a new group annuity table. By June, 1980, the staffing of the individual annuity committee, the "Committee to Recommend a New Mortality Basis for Individual Annuity Valuation,' was complete. ' The charge to the committee, as printed in the Society's Year Book, is as follows:

To evaluate the need for new mortality tables and projection factors and, if it finds a need, develop new tables and/or projection factors. The new mortality tables would be recommended for possible adoption by appropriate authorities for valuation of reserves on individual annuities and settlement option contracts.

The committee reviewed an advance copy of the report "Mortality under Individual Immediate Annuities, Life Income Settlements, and Matured Deferred Annuities between 1971 and 1976 Anniversaries," published in the 1979 Reports Number of the Transactions. The committee compared the 1971-76 experience with the experience that was used as the basis of the

[^0]1971 Individual Annuity Mortality (1971 IAM) Table-in both cases looking at ratios of actual to expected deaths (by amounts of annual income) based on the 1971 IAM Table.

In August, 1980, the committee chairman reported at the meeting of the NAIC (C4) Life, Accident and Health Insurance Technical Subcommittee that, on the basis of preliminary studies, it appeared to the committee that the 1971 table would not be adequate during the 1980s and that a simple age setback would not be appropriate. Further, the slope of the Projection Scale B mortality improvement factors was such that the factors would not adjust adequately for the recent improvement in mortality at the high ages. Any proposed new set of improvement factors would be substantially higher at the older ages.

Table 1 of this report compares the mortality experience used as the basis for the 1971 IAM with the 1971-76 experience on immediate annuities, matured deferred annuities, and settlement options, after adjusting the 1971-76 experience so that it would have the same proportions of exposures by kind of contract as in the 1971 IAM basic data experience. The experience is by amount of annual income, and the mortality ratios are ratios of actual to expected mortality on the 1971 IAM Table.

If we assume that the 1971-76 experience is centered on 1973, then it is apparent that the 1971 IAM already provided less than the desired 10 percent margin at ages 80 and over. Given another ten years of mortality improvement, a new valuation mortality table reflecting improved mortality at the older ages would appear to be needed for the period from 1983. In addition, mortality rates for the United States population and other sources for years

[^1]kinds of annuities. The trend strengthens the perceived need to replace the 1971 IAM Table.

An added reason for recommending a new mortality table is the trend toward permitting higher interest rates for valuation reserves, thus cutting down potential interest margins that could otherwise provide the additional reserves required to provide for increasing longevity. (It should be noted,

however, that under current conditions there are ample margins when valuation interest rates are compared with the rates available on current new investments, in contrast to the situation about three decades ago when valuation and new-money interest rates were much closer together.) Adoption by the states of the concept of dynamic interest rates for valuation may further erode interest rate margins available to cover inadequate or negative mortality margins, increasing the need for an adequate valuation table.

In selecting the experience on which to base a new mortality table, the committee reviewed the decisions made relating to the 1971 IAM Table and the reasoning behind those decisions. The committee then evaluated those reasons and decisions as they would apply to the 1971-76 experience and to current conditions generally. As described below, the committee found itself largely in agreement with the conclusions of the Joint ALC-LIAA Actuarial Committee, which constructed the 1971 IAM Table.

## SELECTION OF SOURCE DATA

Since the experience in the report "Mortality under Individual Immediate Annuities, Life Income Settlements, and Matured Deferred Annuities between 1971 and 1976 Anniversaries" represents the most recent available on individual annuities, there was no question but that it be used to produce a basic table. Because the 1971-76 experience was approximately centered on 1973 and the committee was aiming for a valuation table appropriate for 1982, the first year in which any new table would likely be effective in a fair number of states, it was necessary to project the 1971-76 experience for about ten years.

The second question to be answered was whether to combine the experience under refund and nonrefund immediate annuities, matured deferred annuities, and settlement options, as was done for the 1971 IAM Table, or to revert to the earlier practice of basing an annuity valuation table on only the experience under immediate nonrefund annuities. The reasoning of the Joint Actuarial Committee was reviewed and is briefly summarized in the following paragraph.

The ALC-LIAA Joint Actuarial Committee's objective was 'to develop an annuity mortality table which would be 'safe' . . . for the valuation [emphasis added] of all types of individual annuities, including single premium annuities, life income settlements and matured deferred annuities." The table was not intended as a basis for calculating the gross single considerations to be charged for immediate annuities. It was felt that the "combined immediate annuity and settlement option experience, with suitable margins, was an appropriate broad base for developing a mortality table to be used as a minimum valuation standard for all types of individual annuities." There were, however, some misgivings expressed that implicitly adopting the mix of business reflecting the data submitted by the particular companies contributing to the Society of Actuaries studies was, at least, arbitrary.

This latter point was a source of concern also to the current committee. Its concern was even greater because it found that there was such a substantial change in the-proportions of business in the various annuity and settlement options categories that it was necessary to adjust the 1971-76 experience to the same proportions as the " 1963 " experience on which the 1971 IAM Table was based in order to make a valid mortality comparison. Table 3 shows, for ages $60-69,70-79$ and 80 and over, the ratios of the exposures (by amounts of annual income) in the experience used for the 1963 Experience Table to the corresponding exposures in the 1971-76 experience, by kind of contract.

An analysis was made of the individual company contributions to the studies used to derive the 1963 Experience Table and the contributions to the $1971-76$ study. The analysis is summarized in Table 4. The portion of the total exposure that represented immediate annuities increased from 22 percent in the data underlying the 1963 Experience Table to 32 percent in the 1971-76 study, a result of a dramatic increase in the experience of four of the five largest contributors to both studies. The fifth large company did not contribute any experience to the settlement options or matured deferred annuity portions. All four companies exhibited similar percentage increases. The other companies, which comprised about 50 percent of the immediate annuity experience in the earlier study, did not exhibit this trend and accounted for only 20 percent of the 1971-76 immediate annuity experience.

The decline in the ratio of nonrefund to total refund and nonrefund annuity business from the 1963-67 study to the 1971-76 study was found to be

consistent with respect to each of the companies contributing to both studies. Evidently this is indicative of a real change in the composition of the immediate annuity business.

The committee examined the adjusted total experience, the unadjusted total experience, and that of immediate annuities as shown in Tables 5 and 6. On the basis of this review, the reasoning behind the construction of the 1971 IAM Table, and the feeling that only a substantial difference could justify reverting to the older method of using only immediate nonrefund

annuity experience, the committee decided to base the new table on the total experience under immediate refund and nonrefund annuities, matured deferred annuities, and settlement options. However, pension trust issues were excluded because their mortality was higher than that of non-pension trust issues, and it was felt that the proportion of such business could vary widely from company to company. Excluding such business was felt to be compatible with the aim of constructing a safe table for valuation purposes.

The committee found itself in agreement with the Joint Actuarial Committee on the latter's decision to base the annuity valuation table on amounts of income rather than numbers of contracts, since the financial effect of annuitant mortality is measured by the amount of annual income rather than by number of contracts. The variation by amount of annual income that has been observed in mortality must be taken into account in providing sufficient reserves for future payments.

The committee also found no reason to change from the inclusion of all durations in the experience on which the new valuation table would be based. Admittedly, variations in levels of new issues and in the degree of self-selection exercised by applicants for annuities could affect the level of aggregate mortality (see Table 6 for a comparison of mortality ratios for groups of contract years). Nevertheless it was felt that aggregate would be safer than ultimate mortality, and the material contributed to the 1971-76 study was the best available estimate of the mix of select and ultimate business. If, in a particular company, the valuation actuary believes that the proportion of new, select, annuity business is substantially higher than that in the experience used for the new table, he should make suitable adjustments, such as using an age setback. Similar considerations would apply to a company with a very large proportion of nonrefund immediate annuities.

## THE QUESTION OF SEX-DISTINCT OR UNISEX VALUATION MORTALITY TABLES

The new individual annuity mortality tables are intended for use as valuation tables, that is, to provide a minimum standard for reserves on individual annuities in the aggregate. The committee considered but did not adopt the concept of a single merged gender table as a valuation standard. In making its decision, the committee considered the following points.

If the actual male/female proportions for the annuity business of a particular company are different from those assumed in the construction of a merged gender valuation table, the reserves will be redundant or insufficient depending on whether the actual proportions of male annuitants are greater or smaller.

If a merged gender table were constructed so as to reflect precisely the male/female distribution of a particular company's annuity contracts, then subsequent deviation of male and female mortality from that assumed could make the merged gender table inappropriate at some later time.

## CONSTRUCTION OF THE 1973 EXPERIENCE TABLE

In order to derive a projected 1983 mortality table, it was first necessary to construct experience tables based on the most recent data available. A special tabulation of the Society of Actuaries 1971-76 annuity mortality study was prepared for the committee. Broken down into five-year age groups, the tabulation summarized the data by numbers of contracts and amounts of annual income for contract durations 1 and over (see Table 6).

Combining the data over all kinds of contracts, ratios of actual to expected deaths on the 1971 IAM Table were calculated by five-year age groups for the total of immediate refund and nonrefund annuities, matured deferred annuities, and all settlement options-from death claims, maturities, and surrenders-for contract durations 1 and over, in all cases excluding pension trust business.

The $q_{x}$ 's for each five-year age group were not calculated directly because a test showed that the actual average age of a five-year age group was not always the same as the central age. The test consisted of dividing the expected deaths in each five-year age group by the exposure to obtain the average expected mortality rate. Entering the 1971 IAM Table with the resulting mortality rate showed that the corresponding age was not generally equal to the central age of the five-year age group. Accordingly, to obtain more accurate experience mortality rates at the central ages, the $\mathrm{A} / \mathrm{E}$ mortality ratio for each five-year age group was applied to the 1971 IAM Table $q_{x}$ for the central age of each five-year age group to obtain an experience $q_{x}$ at the central age.

The resulting mortality rates, for males and females separately, were graduated and interpolated by a Jenkins fifth-difference osculatory interpolation formula computer program that included a cubic equation to close out the highest ages with $q_{x}=1$ at age 115. (A Whittaker-Henderson graduation of the mortality ratios was also attempted, with varying weights for smoothness, but the results were unsatisfactory.) The experience from the 1971-76 study yielded mortality rates only at ages over 50 . In fact, the Jenkins formula yielded usable rates only above age 60. It was necessary to look elsewhere for a source of appropriate mortality rates at the younger ages.

Fairly recent United States population mortality rates were available, but the committee felt that population mortality is not expressive of annuitant
experience, which is affected not only by self-selection but likely also by socioeconomic factors. Experience of insured lives seemed to be an acceptable substitute, and the 1980 CSO Table covered the proper time interval. The committee considered and constructed a version of the 1973 Experience Table by using the mortality rates from the 1980 CSO Basic Table ( $K$ Basic Table) at ages 47 and under, with a cubic curve connecting these rates with the graduated 1971-76 combined experience rates at ages 67 and over. However, it appeared to the committee that the resulting mortality rates at the younger ages were somewhat high.

The committee decided to use the 1971 IAM Table mortality rates at ages 47 and under. However, the 1971 IAM Table rates had been loaded for use as a valuation table. If these rates were used without adjustment in the 1973 Experience Table, a second loading would be added in the process of deriving the 1983 Table $a$ from the 1983 Basic Table. To avoid this consequence and at the same time provide for a smooth table through all ages, the 1971 IAM Table rates at ages 47 and under were divided by 0.9 to offset exactly the level 10 percent loading adopted by the committee for the 1983 Table $a$. (The rationale for the level 10 percent loading is described later in this report. It should also be noted that the committee developed the 1983 Table $a$ at the financially important upper ages before adding the mortality rates at the younger ages.)

A cubic curve was used to connect the unloaded 1971 IAM Table mortality rates to the 1971-76 graduated rates at ages 67 and over. The entire set of rates was then regraduated by the Jenkins fifth-difference modified osculatory graduation formula. The resulting 1973 Experience Table mortality rates appear in Table 7.
The graduated 1973 Experience Table was then applied to the exposures of the 1971-76 combined annuity experience. The results are shown in Table 8, which indicates rather close adherence of the 1973 Experience Table to the $1971-76$ experience. Table 15 provides a comparison of the graduated 1973 Experience Table with other annuity tables.

## MORTALITY IMPROVEMENT, 1973-83

When the committee commenced work on the new individual annuity basis project, it was felt that work could be completed by the end of 1981 in time for consideration by the NAIC at its December, 1981, meeting. Approvals by the various states could begin in 1982. Consequently, the committee decided to project the table to 1983 so that it would, at its inception, be as up to date as possible. The committee suggests that the 1983 Table $a$ be reexamined periodically for continuing appropriateness.
As was the case for earlier annuity tables, this committee was hampered

[^4]by a lack of recent, suitable data from which to project mortality improvement rates, since the most recent individual annuity experience was centered around 1973. Published United States population mortality rates through 1978 indicated that mortality at the higher ages had shown much higher rates of improvement in the mid- and later 1970s than in previous years. The committee was given an advance copy of John C. Wilkin's paper "Recent Trends in the Mortality of the Aged," published in this volume of the Transactions. The paper, which reported on the mortality of persons covered under medicare where deaths were matched to exposures and ages were felt to be more accurately reported than in census data, corroborated the higher improvement rates. Annual improvement rates from several different sources are shown in Table 9.

In deriving the 1971 IAM Table, the Joint Actuarial Committee based its choice of mortality improvement rates for the period from 1963-71 on the immediate annuity experience from 1958-63 to 1963-67 and the "settlement annuity" experience from 1955-60 to 1960-65. Annual improvement rates were developed from the combined experience for ages 79 and under ( 1.6 percent) and ages 80 and over ( 1.1 percent). The same rates were used for males and females.

There can be no doubt that there has been a substantial drop in mortality since 1968 , following a marked slowdown in the rate of improvement over the period from the 1950s into the 1960s. Further, whereas the improvement in mortality prior to the 1950s reflected mostly progress against the infectious, acute diseases and benefited mainly the younger ages, the more recent improvements occurred among the chronic ailments of the older agesischemic heart disease, in particular. While it is hard to find complete agreement among epidemiologists as to the cause of the decrease, they agree that the decrease is a fact. They also agree that the decrease in heart-related deaths is real and not a result of changes in diagnostic techniques or coding of cause of death.

Reasons given for the recent improvement range from changes in smoking habits to greater recognition of hypertension and more effective means of treatment and better emergency and post-heart attack care. One writer suggests that the increase in deaths from heart-related disease after 1920 followed the rapid spread of smoking after World War I, while the recent decrease reflects a reduction in smoking.

There has been a decrease in deaths from other causes as well, even from cancer, if lung cancer is excluded.

In view of the continued drop in mortality since 1968 , especially at the very high ages, the use of improvement rates based on prior annuity experience did not seem appropriate for use over the period from 1973 to 1983.

TABLE 9

## Comparison of Annual Improvement Rates in Mortality from Various Sources

* The 1979 experience was based on a 10 percent sample of deaths.
$\dagger$ W. A. Jenkins and E. A. Lew, "A New Mortality Basis for Annuities," TSA, I (1949), 369.

Unfortunately, there was no suitable annuity experience available, subsequent to the 1971-76 study. A review of one large company's recent annuity experience showed inconsistencies and anomalies, probably arising from the effects of class selection in a competitive marketplace, which could have a proportionately greater effect on a single company's experience than on that of several companies combined. The Society's ordinary life insurance experience was not deemed entirely appropriate because of the probable effects of changes in underwriting rules caused by inflation and competitive considerations. This left United States population mortality and medicare experience as likely sources.

The committee considered both United States population data and the medicare data reported in the Wilkin paper, which ably analyzed the data at length and compared the data with United States population experience. The committee found that the improvement rates of the United States white population (males and females separately) for the period 1961-65 to 1971-76 tended to parallel the improvement rate of the total annuity and settlement option experience from the period covered by the 1963 Experience Table data to the 1971-76 study and were of about the same magnitude.

The use of population data to project annuity mortality can be objected to for a number of reasons. There is no self-selection. There are likely to be wide differences in average income levels, occupations, and geographic distributions between the two sets of individuals. Mortality improvement among the population may be largely the result of improvement in average socioeconomic status (mortality is considered a "social indicator''2). Finally, there may be errors in counting or age reporting in the deaths and exposures.

Since the mortality improvement factors measure the change in the mortality of the population, not the mortality itself, they are not likely to be unduly sensitive to differences in composition of the two groups except to the extent that the factors causing the change in mortality reflect changes affecting one socioeconomic group more than another.

While changes in the socioeconomic area may have had some effect, it is believed that over the periods studied, other factors were much more important, particularly at the ages that are financially important in an annuity table. These other factors were evident in the increased rate of improvement observed during the period subsequent to 1971-76.

Improvement rates in the medicare experience at the higher ages were examined, but, since they were available only for white and nonwhite lives combined, it was felt that these rates might be influenced too much by changes in socioeconomic status of the nonwhite population. In fact, a

[^5]comparison of the improvement rates in Table 9 will show that the mortality improvement rates in the female medicare experience from 1973 to 1977 are markedly higher than in any other experience.

After reviewing all the available data, the committee developed a set of improvement rates based largely on the United States white population experience, with some effect given to the medicare experience and the relationship of annuitant to the United States white population improvement rates during the period 1961-65 to 1971-76. The committee also felt that the use of separate male and female improvement rates was not warranted by the available experience for use over the period of projection from 1973 to 1983. A further consideration was the desire of the committee to create a table that, while it would be a safe table to use for valuation when interest rate margins were likely to be thin, would not be so conservative as to cause undue surplus strain on new issues. The final 1973-83 annual improvement factors appear in Table 9.

A distinction by sex will be made in the derivation of projection factors beyond 1983, since they may be in use over a longer period and should reflect past experience over a longer period. The factors used to derive the 1983 Experience Table were based on observed rates that covered half of the period-in fact, the committee also looked at rates through 1977-79, although the 1979 experience was based on only a 10 percent sample of United States population deaths.

For comparison purposes, the Projection B improvement rates have been included in Table 9; the shift by age is apparent. As compared with Projection B, the 1973-83 annual projection rates are higher at ages over 32 and persist into the 90 s , where the Projection $B$ factors grade down to zero. The chosen improvement factors were intended to project recent experience, which, however, may not be indicative of the period beyond 1983.

A discussion on changes in selection by annuitants since 1945 appears in Appendix B.

## THE 1983 BASIC TABLE

Applying the final 1973-83 improvement factors to the 1973 Experience Table produced the 1983 Basic Table (Table 10). For pivotal ages (those ending in 2 and 7) the ten-year (actually 9.5 years) improvement factors were calculated as

$$
\left(1-\frac{\text { annual improvement rate percent }}{100}\right)^{9.5}
$$

The factors were applied to the 1973 Experience Table values at pivotal ages, and then the resulting 1983 pivotal values were graduated and interpolated by the Jenkins modified osculatory interpolation formula with, as

before, a cubic curve to finish off the table at the extreme ages. Table 14 shows the calculation of the mortality rates at ages 5 and 6 for the 1973 Experience Table, the 1983 Basic Table, and 1983 Table $a$. The 1983 Basic Table is compared with recent nonannuity mortality rates in Table 11, and with other annuity mortality rates in Table 15.

## COMPARISON OF 1983 BASIC TABLE WITH RECENT NONANNUITY MORTALITY

Table 11 compares the 1983 Basic Table with the 1980 CSO Basic Table, recent intercompany ordinary life insurance mortality experience, and recent group life insurance experience. The group figures made available to the committee were not yet final.

As compared with ordinary life insurance experience, the 1983 Basic Table has rather comfortable margins at the older male ages and the midrange

[^6]of female ages, with somewhat lesser margins at the older and younger female ages and very thin margins at the younger male ages and at male ages 50-54.

As compared with group life insurance experience, the margins in the 1983 Basic Table are ample at all ages. However, examination of the death rates excluding disability claims indicates that the experience at ages in the 50 s is heavily affected by disability claims.

The mortality rates in the 1983 Basic Table are comfortably below those of the 1971 IAM Table except for male ages in the 70s and 80s (see Table 15). Since the committee was aiming for a valuation table that would be adequate but not overly conservative, these results are in line with expectations. It might be noted, too, that new tax laws that favor increased investment for retirement may make annuities more popular and act to decrease the effect of self-selection in the future.

Subsequent to the selection by the committee of the United States white population mortality improvement rates as the basis for projecting the 1983 Basic Table from the 1973 Experience Table, an error in the underlying United States population estimates was announced by the National Center for Health Statistics (United States Department of Health and Human Services). For years between the 1970 and the 1980 census, NCHS had computed exposures using the prior year's figures, adding births and estimates of net migration and subtracting deaths. The intercensal estimates are routinely checked against census counts every ten years and have been, in the past, fairly close to the actual.

It has now been reported that the estimated 1980 population was less than the census count by almost five million lives. As of this writing, few details are available except that the largest error affects males in the age range 15-34. It is most likely that the error increased with years elapsed since 1970. Under this hypothesis, the annual improvement rates are probably understated by some small amount. Since birth and death records are almost complete, the error must stem from one or more of the following: underestimating net immigration, a very large undercount in 1970, or a much more complete count in 1980. The committee believes that the underestimate would not have had any material effect on the committee's choice of improvement factors, even though they were in large part based on the population data. A rough recalculation on the basis of total population indicates that any resulting understatement of improvement factors is of the order of two-hundredths of 1 percent. Table 12, an exhibit prepared by the Statistical Bureau of the Metropolitan Life Insurance Company, is of interest. It shows several sets of improvement rates and their effects projected to 1985, 1990, 1995, and 2000.

TABLE 12-Females-Continued
PROJECTED DEATH RATES PER $\mathbf{1 0 0 , 0 0 0}$

To provide a safe mortality table for valuation purposes, it is necessary to provide a margin over the experience rates. The purpose of the margin may be defined variously as providing for variations in mortality levels by company, variations between different types of contracts (e.g., refund versus nonrefund immediate annuities) and different levels of mortality because of variations in a company's mix of business, fluctuations in mortality from year to year, and, to some extent, a future decrease in mortality of annuitants, although the preferred method would be to recognize this improvement directly through the use of mortality improvement factors.

In its deliberations on the form and amount of the loading, the committee considered the use of a nonlevel loading formula that would vary by age. In particular, the committee considered the use of a loading formula that would decrease the percentage loading at the ages above, say, age 70. Nonlevel loading formulas considered were of the form $0.10 e_{x} / e_{70}$ at ages over 70, or a linear function of age providing for a reduction in the loading at the higher ages. It was felt that the $0.10 e_{x} / e_{70}$ function would provide too rapid a falloff in loading, while the linear function would be more gradual. It was also noted that in the process of applying a flat loading to the experience table and regraduating, the loading would diminish toward the very end of the table as a result of the graduation process.

In order to test the adequacy and appropriateness of a flat 10 percent loading, an approximate test was made for the companies that contributed to the 1971-76 annuity mortality study.

The total nonpension experience for males and females combined produced a mortality ratio of 107 percent of the 1971 IAM Table. A 10 percent safety margin lowers the ratio to 96 percent of the 1971 IAM Table. Table 13 shows the mortality ratios of ten companies that contributed data to the 1971-76 annuity mortality study. The experience of all but companies C, E, and J is covered by the loaded experience, and only Company C falls very far under the 96 percent limit.
The committee finally rejected any variation by age, noting that the primary reason for the loading was to cover variations in mortality between companies. A secondary purpose of the loading is to provide for variations in mortality from year to year, and the committee felt that there was a greater chance of fluctuation at the highest ages where the number of lives would be fewer and less confidence could be placed in the mortality experience. The committee also felt that weight should be given to the choice of a 10 percent level loading in the 1971 IAM. The committee noted that, on the basis of the 1971-76 combined immediate annuity experience, a 10

* Ten companies.
percent loading factor would have provided a safe table for most of the companies contributing to the 1971-76 Society of Actuaries mortality study. Basing its judgment on the foregoing considerations, the committee agreed that a level 10 percent loading was the preferred approach.

## HIGH AGE MORTALITY

## Tabular Mortality Rates at the Very High Ages

As is customary in ending a valuation mortality table, the 1983 Table $a$ mortality rates at ages above 97 were obtained by fitting a cubic curve from age 97 to age 115 , with the value of $q_{x}$ at age 115 taken as 1.000 . This method is satisfactory in that it provides for graded mortality rates at the extreme ages where the precise values have little effect on monetary values at the important ages under 100 .

It is suggested, however, that in the construction of future mortality tables this procedure be replaced by the use of more accurate experience mortality rates that will likely be available from sources such as medicare and special follow-up studies. A private communication received by the chairman shows that mortality apparently does not continue to increase at ages over 100 but rather tends to level off at about 30 percent. Unfortunately, these data are not yet sufficiently substantiated that the committee could make use of the rates developed. Otherwise the 1983 Table $a$ could have been terminated
by using 300 deaths per thousand for males at ages 102 and higher and at ages 104 and higher for females, in each case terminating at age 115 with $q_{x}$ set at 1.000 . The table below shows the effect on values of $a_{x}$ at ages 65, 75,85 , and 95.

Values of $a_{x}$ at 7 Percent Interest

FINAL GRADUATION OF THE 1983 TABLE $\boldsymbol{a}$
The 10 percent loading was subtracted from the 1983 Basic Table at pivotal ages. The resulting rates were then graduated by the Jenkins modified osculatory fifth-difference interpolation formula. The calculation of mortality rates at ages 5 and 6 is shown in Table 14. The table was closed off at the high ages by means of a cubic curve with $q_{11 s}=1.000$. The 1983 Table $a$ mortality rates appear in Table 16; a comparison with other annuity mortality

rates appears in Table 15. Graphs comparing the 1983 Table $a$ with the 1971 IAM Table and the 1980 CSO Basic Table appear in Figures 1 and 2.

At its June, 1981, meeting, the NAIC (C4) Life, Accident, and Health Insurance Technical Subcommittee expressed a desire that the 1983 Table $a$ be expressible by a mathematical formula, noting that the 1980 CSO tables had been expressed as a 20 -term formula. If a formula had to be found for the 1983 Table $a$, the best time to do so would be before its final adoption, when minor variations would be acceptable in view of the ability to use a fairly simple formula.

The committee attempted to use a formula of the kind described by L. Heligman and J. H. Pollard in "The Age Pattern of Mortality.'" The authors were able to fit the formula

$$
q_{x} / p_{x}=A^{(x+B) c}+D \exp \left[-E(\ln x-\ln F)^{2}\right]+G H^{x}
$$

rather closely to Australian population mortality rates. The three parts of the Heligman-Pollard formula consist of (1) a Gompertz function for the high ages, (2) a lognormal function to cover the accident hazard at the young adult ages, and (3) a sharply reducing exponential function for the childhood ages.

The form of the equation is unchanged whether the function graduated is $q_{x} / p_{x}$ or colog $p_{x}$. The committee attempted to fit a comparable formula to the 1983 Table $a$ values, first to values of $q_{x} / p_{x}$ and then to $\operatorname{colog} p_{x}$.

At the higher ages, the Heligman-Pollard formula rates are provided mainly by the Gompertz function, $G H^{x}$, to represent colog $p_{x}$. A leastsquares method was used first to derive the values of $G H^{x}$. When these had been obtained, the lognormal segment was then estimated, and finally the first term of the formula (omitting the $B$ term) was fitted to the values for ages 5 and 6.

While it was possible to achieve a close fit at the younger ages, especially on a relative basis $\left(\Delta / q_{x}\right)$, it was not possible to obtain a satisfactory fit ( $\pm 2.5$ percent) for the Gompertz function at the important ages $60-92$. This may be attributed in part to the use of the discontinuously varying "improvement factors'' (described above) to reflect improvements in mortality over the period 1973-83. The original raw data followed an exponential more closely.

When graphed on semilog paper, the 1983 Table $a$ mortality rates fell below a least-squares straight line at the lower and upper age ranges of 60 through the 90 s. In an attempt to correct for this, a function of the form $x^{1 / n / K}$ was applied to $G H^{x}$, where $n$ was arbitrary and $K$ was chosen so that $x^{1 / n} / K$ was equal to unity at some pivotal age where no correction was desiríed. Values for $n$ of $2,4,6$, and 8 were tried, and different pivotal ages were used, but it appeared that no such simple expedient could improve one segment of the Gompertz function without worsening another. The attempt to define the new mortality table in terms of a reasonable mathematical formula was reluctantly abandoned.

Life table values and commutation columns at 5, 7, and 9 percent interest appear in Appendix A.

[^8]
## COMPARISON OF ANNUITY VALUES 1983 TABLE $a$ VERSUS 1971 IAM TABLE

Values of (1) life annuities, (2) annuities for ten years certain and life and (3) twenty years certain and life at 5, 7, and 9 percent on the 1983 Table $a$ and the 1971 IAM Table are shown in Table 17. Ratios of 1983 Table $a$ values to 1971 IAM Table values are shown to indicate how much reserves will increase under the new table. (A model office comparison is described in the following section.) Values are shown for every fifth age from 60 to 95.

As might be expected, the percentage increases are greater when interest is at 5 percent than at 7 percent and 9 percent. The percentage differences also increase with age for life annuities, a result of the improvement factors at the older ages. For annuities with ten years certain the percentage differences decrease with age as the effect of the certain annuity outweighs the contribution of the deferred annuity. This effect is more pronounced for annuities with twenty years certain and at the higher interest rates.

At 5 percent interest, 1983 Table $a$ life annuity values are about 5-7 percent higher than those on the 1971 IAM Table for males at ages $60-75$, and $5-10$ percent higher for females at ages $60-75$. The percentage increases are greatest at the very high ages, where they exceed 20 percent. At male age 95 , there is a 50 percent increase in the life annuity value at all three interest rates. The reserve, however, increases only from about $12 / 3$ times the annual payment to about $21 / 2$ times the annual payment.

To test the effect of carrying reserves at a lower interest rate on the 1971 IAM Table rather than on the 1983 Table $a$ at an interest rate closer to the earned rate, ratios of 7 percent IAM Table annuity values to 9 percent 1983 Table $a$ values were calculated. These ratios have been interpreted in Table 17A to show as a percentage of the 9 percent 1983 Table $a$ values how much the 7 percent 1971 IAM Table values fall short of $(-)$ or exceed $(+)$ the 1983 Table $a$ values. Table 17A indicates that an interest differential of somewhat less than 2 percent would be sufficient for life annuities. For annuities with ten years certain and twenty years certain, it is evident that the $n$-year certain annuity portion outweighs the deferred life annuity portion.

## MODEL OFFICE RESERVE TEST

In order to show the aggregate effect on reserves of valuing on the 1983 Table $a$ rather than on the 1971 IAM Table, a model office was constructed and reserves on both tables were calculated at 5,7 , and 9 percent. The results of the model office analysis appear in Table 18.

As a basis for the model office, the exposures from the 1971-76 study (contract years 1-5) were used as the first-year in-force of a typical company. Values of ${ }_{s} p_{x}$ at the central age of each five-year age group from the 1983 Basic Table were used to age the in-force over a period of twenty years. A computer program was written to apply reserve values to the in-forces at each five-year interval. Annuity values for ten years certain and life thereafter were used for all refund annuities. Simpson's rule was used to obtain a sum over the entire period. The results, as percentages of 1983 Table $a$ reserves over 1971 IAM Table reserves, are shown for each kind of annuity business and for all combined. Admittedly certain liberties were taken with the calculation of the aggregate reserves-for example, the use of an elevenyear period and a twenty-one-year period-to simplify the calculations. The results should, of course, be regarded as illustrative only.

At 5 percent interest, the 1983 Table $a$ aggregate reserves were about 8 percentage points higher than those on the 1971 IAM Table over eleven years, and 10 percentage points higher over twenty-one years. The 1983 Table $a$ female reserves as compared with 1971 IAM Table female reserves were about 2 percentage points higher than for male reserves.

At 7 percent interest, the 1983 Table $a$ reserves as compared with the 1971 IAM Table reserves were about 7 percentage points higher over eleven years, and 9-10 percentage points higher over twenty-one years. The ratios were generally about 1 percentage point lower than those for 5 percent. Similarly, the ratios for 9 percent reserves were about 1 percentage point lower than those for 7 percent reserves and about 2 percentage points below those for 5 percent reserves.

## FUTURE MORTALITY IMPROVEMENT—SOME GENERAL CONSIDERATIONS

Dr. James M. Fries, in his article "Aging, Natural Death and the Compression of Morbidity, ${ }^{, 4}$ comments on the interaction between two sets of ob-servations-first, that the length of life is fixed (or may increase at the rate of one month per century) and, second, that chronic disease may be postponed, thus decreasing the period by which one falls short of the expected length of life, which he estimates at around 85 . He points out that if one assumes a normal distribution of deaths around such an age, there would be some survivals beyond age 100 , but not many would exceed that age. Most of the improvement in survival, Fries points out, has been at the neonatal and younger ages, with relatively little improvement at the older ages, where the chronic diseases are important.

Fries justifies his view of a limit on the length of life mainly on the grounds of loss of organ reserve with increasing age and the consequent inability of the body to restore itself after some threat to its continued health. However, he states that the chronic diseases can be postponed so that not only premature death (i.e., death prior to the expected age) will be prevented or postponed, but also chronic morbidity will be postponed and its duration until death shortened. The reasons, he asserts, lie in effective treatment of hypertension, exercise as an answer to arthritis and heart disease, a decrease in smoking causing a postponement in chronic obstructive pulmonary disorders, and a changing way of life stressing personal choice, all helping to postpone the onset of disabling disease.

According to the Fries viewpoint, we may look to decreases in mortality that will continue but will lessen with increase in age. This concept would favor a set of projection factors much like Projection B. However, this conclusion must be contrasted with the recent decreases in mortality in the United States white population and in the medicare experience.

Further refutation of the idea of little improvement in mortality of the extreme aged appears in Ira Rosenwaike, Nurit Yaffe, and Philip C. Sagi, "The Recent Decline in Mortality of the Extreme Aged: An Analysis of Statistical Data.' ${ }^{\prime}$ (Since this article relies on intercensal estimates of the United States population during the 1970s, it should be kept in mind that the populations were understated as noted earlier in this report and consequently the improvement rates during the 1970s may be slightly understated, although probably by a negligible amount at these very high ages.) The authors also make use of medicare data to develop their analyses. According to their analysis of medicare as compared with Census Bureau

[^9]estimates of population, some, but certainly not the greater part, of the substantial drop from 1966 to 1977 among those 85 and over is probably due to age misstatements and other errors. This is illustrated in Table 19, which compares (1) mortality rates and (2) percentage changes in mortality rates, by cause of death, for the United States white population using Census Bureau and medicare data in the denominators of the mortality rates.

Over the period 1968-77, the same cause-of-death coding instructions were in effect, so coding of cause of death would have had no material effect on the decreases noted above. Because diseases of the heart and cerebrovascular disease are together such an important part of the total death rate at these advanced ages, any appreciable improvement in the death rate from these causes would have considerable impact. Rosenwaike et al. attribute to Stamler and others the opinion that the sharp downturn in cardiovascular disease mortality is due to "progress in controlling such risk factors as high saturated fat and cholesterol diets, cigarette smoking and hypertension," which prevents or postpones cardiovascular disease, plus, on the other hand, more effective "emergency, acute and long term care for patients with coronary heart disease and stroke."

Another writer, however, concludes that there is no single cause or combination of causes that accounts for the recent decline in ischemic heart disease. Analyzing the rise in the death rate from 1920 to the 1950s and the sharp decline in the 1970s, Reuel A. Stallones ${ }^{6}$ can find nothing to account for the rise and fall, with the possible exception of cigarette smoking, which increased and decreased over the same period. He does not believe that increased exercise, diet control, treatment of hypertension, or better emer-

TABLE 19

[^10]gency care could have had the widespread effects needed to explain the decline. Even though Stallones cannot cite a logical cause for the decline, he nevertheless believes that the decline is real and not an artifact.

Stallones does, however, note that "the decrease in the risk of death from acute myocardial infarction for women is sharply at odds with the popular supposition that the redefinition of women's roles in American society (in particular their appearance in large numbers in executive offices around the country) will result in redistribution in their pattern of illness. Increases in peptic ulcer and in myocardial infarction are projected and sometimes cited. Since the mortality from peptic ulcer is decreasing as steeply as the mortality from myocardial infarction, the thesis appears to be contradicted by the observations."

In October, 1978, a Conference on the Decline in Coronary Heart Disease Mortality ${ }^{7}$ was held to analyze the drop in mortality from various heartrelated causes. Some of this analysis is particularly pertinent to the projection of mortality improvement rates after 1983 and will be summarized below.

Harry M. Rosenberg and A. Joan Klebba, in "Trends in Cardiovascular Mortality, with a Focus on Ischemic Heart Disease: United States, 1950-76,'8 comment that for the total United States population over the period 1968-76 almost every cause of death in the category major cardiovascular diseases "showed substantial reductions in mortality" on an ageadjusted basis. The percentage reductions ranged from 21 percent for ischemic heart disease to 50 percent for hypertensive heart disease and almost as much for hypertension. Only the residual group showed an increase. Table 20 illustrates recent annual changes in mortality for two important

TABLE 20
Annual Change-United States White Population, 1968-76

| Age Group | acute Myocardial Infarction |  | Chronic ischemic Heart Disease |  |

| 75-84 | -2.5 | -3.0 | - . 8 | $-1.9$ |
| 85 and over | -3.9 | -4.2 | -1.4 | $-2.2$ |

[^11]categories of heart disease. The importance of Table 20 in future projections of mortality lies in the fact that these two causes account for two-thirds of the total cardiovascular deaths and one-third of the deaths from all causes. It should also be noted that, while the female improvement rates are somewhat greater than male at the older ages for acute myocardial infarction, they are about double for chronic ischemic heart disease, which is the more important of the two at these older ages. At ages under 75, mortality from acute myocardial infarction is much the more important of the two.
Finally, Dr. Nemat O. Borhani, in his discussion "Mortality Trend in Hypertension, United States, 1950-1976," as another part of the Conference on the Decline in Coronary Heart Disease Mortality, comments that "mortality from hypertension and hypertensive heart disease has declined steadily and dramatically since $1950^{\prime \prime}$ and that mortality from the latter cause has dropped during this period by 81 percent; the largest percentage decline was observed among white females, which he claims may be due to higher percentage changes in awareness and control of hypertension among women.
In any case, Dr. Borhani attributes the reduction in mortality not to a decrease in prevalence rates but rather to a much increased public awareness of hypertension and an increase in the percentage of persons with hypertension who were being adequately treated. While the awareness and treatment percentage increase was greatest among white women, there were increases also among the other race/sex groups. Dr. Borhani attributes about 40-48 percent of the decline in mortality to these changes in public awareness, changes in physicians' attitudes, and efficacy of treatment.
If, in fact, the reduction in cardiovascular mortality does reflect improved awareness of and effective treatment for hypertension, then there is a good possibility for further reduction in the death rate, with perhaps, however, a greater effect among race/sex groups other than white females, where the percentages of awareness and treatment are already quite high.
Cancer, in all its forms, presents a less hopeful picture for considerable future improvement, but at the more advanced ages it is not nearly as important as the cardiovascular group of causes of death. In the absence of a breakthrough of some kind, it appears unlikely that there will be any sharp downward shift in mortality from cancer. If smoking declines in the future or if the use and/or effectiveness of low tar/low nicotine cigarettes increases proportionately among those who continue to smoke, there may be future declines in lung cancer, which, when combined with the decline in other cancer mortality, will lead to lower cancer mortality overall. Cer-

[^12]tainly at the older ages, no significant contribution to any overall reduction in mortality can be expected from the causes grouped under cancer (all forms).

## MORTALITY PROJECTION BEYOND 1983

The close relationship between the annual improvement rates from the " 1963 " annuity experience to the 1971-76 annuity experience and that of the corresponding United States white population was noted in the discussion leading to the decision to base the 1973-83 improvement factors mainly on the population experience. In going beyond 1983, recent population experience will be relied upon largely, although other sources will also be referred to in selecting likely improvement rates-for example, recent ordinary insurance experience and the 1980 Social Security Administration projections.

The preceding section discussed at length recent expert opinion on trends in mortality from cardiovascular disease and also included a few comments on changes in cancer death rates, notably on the decrease in mortality from cancer excluding lung cancer. The Statistical Bureau of the Metropolitan Life Insurance Company prepared an analysis of the changes in mortality rates among the United States white population during the period 1968-78 for major causes of death. These analyses corroborated the opinions on heart and circulatory deaths and on cancer deaths. The analyses show substantial decreases with respect to several other important cause-of-death groups.

According to the Statistical Bureau analyses, there were decreases of generally 25-35 percent and more in the death rate from diabetes with higher decreases in the influenza and pneumonia death rates and deaths from bronchitis, emphysema, and asthma. Deaths from accidents decreased about $20-35$ percent at ages over 39 and at the childhood ages. The mortality of young adults either worsened or did not show appreciable change during the period. The suicide death rate increased considerably at the young adult and teen years. Homicides were up substantially over a wide range of ages.

It would appear likely that the distribution by cause of death for annuitants would be quite different from that of the United States population. Just the difference in average socioeconomic level between the two groups could have an effect. Unfortunately, no cause-of-death analysis is available for annuitants, and consequently any projection for the future will have to be on the basis of a judicious weighing of the relation of change in mortality by cause to total change in the mortality of annuitants. In any case the reasonableness of the set of future mortality improvement factors must rest
on their relationship to changes by cause of death. A projection of future United States mortality using cause-of-death analyses was used in the 1980 projection of United States social security populations. ${ }^{10}$ The result of using this method was computed by the committee and appears in Table 21.

Admittedly, a change in the average socioeconomic status of annuitants could have a significant effect on the future mortality experienced under annuities, as could a lessening of self-selection in the purchase of an annuity or in the decision to take the value of a matured deferred annuity or settlement option in the form of a refund or nonrefund annuity. While it is not possible to estimate changes of this type, it seems reasonable to assume that under the newly adopted tax laws in the United States there may well be additional incentives for the use of annuities as retirement savings vehicles. Certainly there would appear to be no reason to assume increasing annuitant selection in purchasing annuities. Accordingly, the prime forces affecting annuitant mortality would seem to be those influences that affect the mortality of the population as a whole.

[^13]
## BEYOND 1983

From the foregoing discussions, it is reasonable to state that, for the foreseeable future, mortality at most ages will continue to improve. While nothing in the way of a "breakthrough" in the treatment of cancer or heart and circulatory diseases is indicated or assumed, continuation of and improvement in current detection and treatment methods will almost certainly result in continued decreases in death rates from these diseases, although probably not at the levels of the 1970 s. There are indications of continued progress in prevention and treatment of other diseases also.

Mortality in the teen years and in the twenties largely reflects life-style, and there is nothing to indicate any great change from current levels. At the childhood ages, some future improvement should be expected, but probably not at a rate as high as in the 1970s.

As the United States population mortality experience of 1980 (see Table 12) indicates, there will also be periods of somewhat increased mortality, especially in years of influenza epidemics. Any set of future improvement rates must take into consideration that there will be periods of retrogression and no improvement in addition to periods of greater than average improvement.

The discussion relative to Table 4 indicated not only a trend toward increased immediate annuity in-forces but also a trend toward a greater proportion of refund annuities. The latter trend and the recent United States tax legislation portend the probability of less self-selection by annuitants (but see Appendix B). If this continues, it could act to reduce the rate of improvement in overall annuitant mortality. The set of improvement factors identified as Projection Scale G in Table 22 is intended to reflect probable average improvement rates through the next decade or so. Table 22 also shows some other improvement rates for comparison purposes.

The Projection Scale G factors are generally somewhat lower than those used to obtain the 1983 Basic Table from the 1973 Experience Table, except that some small improvement is anticipated in the teens and young adult years. Improvement rates for males are somewhat lower than those for females. (The projection factors used to obtain the 1983 Basic Table were the same for males and females. As noted earlier in this report, this was because the committee, in reviewing a set of improvement rates that were different for males and females, felt that the differences were not significant considering the nature of the underlying data and were not sufficient to justify separate improvement rates over a relatively short period.)

The Projection Scale G improvement rates continue to ages in the 90s at rates of 1.25 percent for females and 1.00 percent for males; increase slightly
down to the 40 s , where the rates are 2.25 percent and 2.00 percent for females and males, respectively; and then decrease rapidly to very low rates in the teen years for males. The rates have been set at a level that should keep the 1983 Table $a$ (with projection) reasonably up to date during the remainder of the century but not cause it to become unduly conservative.

The committee is indebted to the Equitable Life Assurance Society of the United States for preparing special tabulations and studies for the committee and to the Statistical Bureau and the Word Processing Unit of the Metropolitan Life Insurance Company. Special thanks are due to Robert Finkelman, a student of the Society, who prepared many of the tables, and to Joseph Shipman, a summer actuarial student, both at Metropolitan Life Insurance Company. Last, but far from least, appreciation is expressed to Dorothy Bailey, secretary to the chairman, for typing numerous versions of text and tables.

## APPENDIX B

## EFFECTS OF SELECTION

Self-selection by prospective annuitants can have an important effect on annuitant mortality experience. It is evident in the overall mortality of annuitants as a class, in the relatively lower mortality under (1) nonrefund contracts as compared with refund contracts and (2) payee elections on settlement options as opposed to nonpayee elections. Selection is evident, too, in the early durations under annuity contracts.

Select mortality in the early contract years affects aggregate mortality if there has been a considerable increase in new issues or if there is an increase in the selectivity exercised by annuitants. Since the effect of selection could be important as to whether an annuity mortality table will be suitable for valuation in the future, an attempt was made to measure changes in selection over an extended period.

Using data published in the report "Mortality under Individual Immediate Annuities, Life Income Settlements, and Matured Deferred Annuities" (TSA, 1979 Reports), ratios of the mortality ratios (on the $a-1949$ Table ) in the first five contract years to those of contract years 6 and over were computed for each study period from 1945 to 1976. These ratios appear in Tables B1, B2, and B3. Since long-term trends were not readily apparent from these results, averages of the first three periods and the last three periods were calculated.

From these averages it appears that there has been some increase in selection under refund annuities-slight under immediate annuities and for females under settlement options and somewhat greater under matured deferred annuities. Selection also increased somewhat for females under nonrefund immediate annuities. Selection was less for males under nonrefund immediate annuities and for both males and females under nonrefund matured deferred annuities.

On an overall basis, the amount of selection is still not great under the refund experience generally, but it bears watching for any continuation of the trend. The trend of selection can be regarded as mixed under the nonrefund experience, where the effect of selection is of much greater magnitude.

To the extent that the 1973-83 improvement factors were based mainly on improvement experienced by the United States white population, the factors could be understated if there were an appreciable increase in selection by annuitants. The results of the above analysis, however, indicate that over the ten-year period it is not likely that a change in selection exercised by annuitants would, in the aggregate, have exercised much greater influ-
ence on the improvement in annuitant mortality than the improvement in the general population death rate, which, in the earlier periods, matched rather well with that of aggregate annuitant mortality.

Table B4 illustrates the effect on immediate annuity values of 90 percent assumed select mortality over the first five and the first ten years after issue.

## DISCUSSION OF PRECEDING PAPER

## JOHN H. COOK:

Mr. Johansen and the members of his committee are to be commended for their excellent work in developing the mortality table which they identify as the 1983 Table $a$ for Individual Annuity Valuation. I am impressed with the careful consideration that they devoted to the mortality rates in that table for young adult ages. It is not typical for actuaries to have great concern about the level of mortality rates in an annuity table for ages under 50 . It is usually felt that the impact of a change in mortality rates at those ages is insignificant. In spite of this, I know that the committee members devoted a great deal of energy to the consideration of the mortality curve for their table in the young adult age range.

It is also a common interpretation that minor variations in mortality rates at ages over 80 have little financial impact on life insurance functions and annuity functions in the upper middle age range. Premium rates for life insurance at age 50 are affected very little by mortality rates after age $\mathbf{8 0}$. Reserve liability for annuity benefits under age 60 are influenced very little by variations in mortality levels after age 80 . Unit life insurance reserves at ages over 80 , especially on paid-up benefits, can be greatly influenced by the mortality rates in the valuation table. In spite of this, aggregate life reserves are very little affected, since the bulk of the valuation in-force for life benefits is for ages under 80.

In the case of annuity benefits at ages over 80 , the valuation reserve is highly sensitive to the mortality rates. In this case, the aggregate annuity reserve is also sensitive, although to a lesser degree, to these same mortality rates. I know that Mr. Johansen and his committee gave careful consideration to the mortality level in the 1983 Table $a$ for the ages over 80 . It has been traditional to assume a terminal age for a mortality table and to develop a table of mortality rates in the latter part of the age range that represent nothing more than a graduation between the last "reliable" value and the value at the terminal age. There is a wide degree of variation concerning the age that is interpreted to represent the oldest-age "reliable" value.

In recent years there has been use of expressions such as the "squaring off of the mortality curve." This implies that improvements in mortality continue through the ages up to retirement and for some years thereafter.

As we approach the end of the table (according to the theory), mortality rates rapidly approach unity. The result of this is an increase in the expectation of life but no increase in the maximum life span.

More recently the theory has been expressed that there is a flattening of the mortality curve at the advanced ages. This theory suggests that mortality rates continue to increase until they reach a level of about 300 per thousand, and then the curve flattens out and the rate does not increase much beyond that. Here we have not only an increase in the expectation of life but also an increase in the maximum life span, although the probability of survival for ten years at that mortality rate is less than 3 percent.

The difference between the two theories is relatively unimportant in life insurance reserve valuation. It is very important in annuity reserve valuation. The report of Mr. Johansen's committee was considered in public forum at the annual meeting of the Society of Actuaries in Atlanta on October 19, 1981. One week before I left the office to attend that meeting, I did not have any particular opinion or concern about the level of mortality at the advanced ages for the 1983 Table $a$. Two or three days before I left the office for that meeting, I learned by chance of some insured life mortality experience that caused me to take a much keener interest in the mortality rates for annuity valuation at the advanced ages.

The mortality experience that became available to me was limited in volume and, accordingly, is subject to the error of statistical fluctuation. The phenomenon that I stumbled across was that the experience rate of mortality in my own company, for certain blocks of business between anniversaries in 1975 and 1980, has been essentially no higher for attained ages 80 and over than for attained ages 75-79. Both of these experience rates are low, and they are significantly below the male rate for age 80 in the 1983 Table $a$.

What I wish to emphasize is that the experience that I report was insured life mortality. It was not annuitant mortality. Furthermore, it was insured life mortality in the ultimate period, excluding the first fifteen durations. I have subsequently examined the experience at durations 11-15 for the same experience period at the same attained ages. That analysis expands the volume of exposure, but of course it reflects the influence of selection standards to a much greater degree. The increased volume of exposure continues to exhibit the trend to lower levels of mortality at the advanced ages than are customarily anticipated.

When I make a statement such as this, it suggests certain obvious questions. One such question is why the 1965-70 Basic Table has such high rates of mortality for the ultimate period at these ages, if the experience of my own company is so much more favorable. Another similar question is, why
does the annual standard ordinary intercompany mortality report of ultimate experience at these ages show a higher level of mortality than I referred to? Another question is, why does the 1980 CSO Table list a higher mortality level at these ages?

Each of these questions is quite appropriate to ask under the circumstances. I have a partial response to each one of these questions, although I do not have a complete and satisfactory understanding of the relationships involving the various mortality experiences. In the first place, the 1965-70 Basic Table reflects intercompany experience for a period ten years prior to the period for which I am reporting. There has been substantial mortality improvement during these ten years. I have examined the intercompany ultimate experience for ages over 75 covering the period between anniversaries in 1975 and 1979. The intercompany experience up to anniversaries in 1980 has not yet been assembled. The four-year period of intercompany experience reflects mortality trends that are consistent with traditional expectations. The difference between this experience and the observed data in my own company I interpret to result from the nature of the business I was analyzing.

The intercompany study includes all contributions for business at durations 16 and over, and it is highly influenced by the experience of business issued more than twenty-five or thirty years ago. My own company data in this instance were limited to policies issued in 1960 and later. This meant that all the business that I was analyzing had been issued at ages 60 and over. Additionally, it was drawn from a block of business that was subject to different and somewhat more stringent selection criteria than what we had applied in 1959 and earlier. The combination of these two facts resulted in more favorable mortality experience than the average. The class of business from which the experience was drawn exhibits generally more favorable mortality than our other blocks of business. The selection standards at the advanced ages at issue are of necessity more severe.

In this connection it is interesting to note that the percentage of insurance applications submitted at ages 60 and over and acceptable at standard rates is low. According to industry data, an all-ages average indicates that about 92 percent of applicants are acceptable at standard rates. This percentage, however, is highly sensitive to age. I do not know what the statistics are for other companies, but in my own company the rate of standard acceptances at age 60 is approximately one-third of the rate at age 20 . Above age 60 the acceptance rate drops rapidly and is only one-half as much at age 65 as it is at age 60. I have been told that this is a demonstration that our selection standards are too severe at the advanced ages. I defend our selection standards, however, because I believe it is necessary, in order to be
both equitable and financially secure, that a block of business issued at the same rates must consist essentially of a homogeneous set of insured lives. It is impossible to establish selection standards at ages above 60 that will admit anything like 50 percent of applicants without having an excessive mortality differential between the best and the worst accepted risk.

Evidence of this variation is readily apparent when one examines the select mortality rates in the intercompany basic table. The mortality for policy year one at ages over 65 is only about 30 percent of ultimate mortality at the same attained age. It is less than 60 percent of the mortality at the same attained age for business issued five years younger. The only explanation for this is that a large percentage of those lives meeting selection standards at the advanced ages become impaired and subject to mortality in excess of the ultimate rate within a short period of time after issue. In fact, I have reason to believe that more than 10 percent of those qualifying for standard insurance at age 60 are unable to meet selection standards one year later.

Why does the 1980 CSO Table contain mortality rates that increase in geometric fashion for ages over 75? That table is based on the intercompany experience between anniversaries in 1970 and 1975. This includes all durations, omitting only the first five. The resultant table does not appear to be representative of the high-attained-age mortality on more recently underwritten business in my own company.

These statistics that I report are facts. The analyses I submit are perhaps no better than subjective determinations. The significance that I attach to these determinations is that companies should be prepared to observe some typical twists in mortality at the advanced ages in the future. The impact of this is not likely to be significant in terms of the financial analysis of life insurance business. It is possible that it will have far greater significance in the financial analysis of annuity business.

## JAMES L. COWEN:

The report of the Committee to Recommend a New Mortality Basis for Individual Annuity Valuation is an excellent piece of work and should serve the purposes for which the new table is intended.

It is unfortunate that the actual experience for 1971-76 on which the table is based is not as current as would be desirable. This is especially true since all or practically all mortality experience studies made through the 1970s have shown continuing improvement in mortality rates, especially at the older ages. However, the procedures used to project the mortality improvement from the 1971-76 experience appear to be reasonable, so there should be little problem with respect to the mortality improvement projection.

Another question, however, is whether the distribution between types of annuities (immediate annuities, matured deferred annuities, and life income settlement options) that existed in the period $1971-76$ is going to continue. I have a feeling that matured deferred annuities may become a more important part of this experience in the future. Under the Employee Retirement Income Security Act of 1974 (ERISA) when a pension plan terminates, among other options, the plan sponsor can let the Pension Benefit Guaranty Corporation (PBGC) take over the payment of guaranteed benefits, or he can purchase deferred annuities from an insurance company. In 1980 I was involved with the termination of two pension plans totaling about 1,200 active lives for which both immediate and deferred annuities were purchased depending on whether employees met the eligibility conditions for retirement. Little, if any, of this type of deferred annuity would be represented in the 1971-76 experience, since ERISA was not enacted until September 1974. It is also probable that this type of annuity purchase will not show the same degree of antiselection shown by other annuities.

The report states that there are many theories about what is causing the mortality improvement at the older ages, and I would like to express mine. Simply put, I feel that the major cause of the mortality improvement has been the inception of medicare and medicaid. The first benefits under medicare were paid in July, 1966, and the mortality improvement began with the 1968 experience.

The advent of medicare has made medical treatment more readily available to the elderly and made them more aware of their medical problems. This goes along with Dr. Borhani's theory of increased public awareness, quoted in the report. Improved health due to better medical treatment also would make the elderly more active, which would complete the circle, since activity helps keep people healthy. Both the increased longevity and improved health have made communities aware of the need to provide activities for the elderly.

If my theory is correct, there should be a lag correlation between improving mortality and medicare utilization. This is a study that someone in the Health Care Financing Administration of the Department of Health and Human Resources should institute.

## EDWARD A. LEW:

In my judgment, this report sets a new standard for papers on annuitant mortality. I assume it will be published in the Transactions, so that together with the discussion it will serve as a source of ready reference on the subject for many years to come and also as a model for future studies of annuitant mortality. Periodic investigations of the experience among annuitants of
various kinds, and in the general population, will be needed if the downward trend in mortality continues.

The report relies in large part for its conclusions concerning the appropriate level of death rates for valuation purposes on information other than annuitant experience. It leans heavily on the paper "Recent Trends in the Mortality of the Aged' by John C. Wilkin (published in this issue of the Transactions, p. 11), which provides the most accurate data currently available on recent population death rates past age 65 and particularly past age 85.

The private communication referred to in the report came from me. It spoke of the findings of an American Cancer Society study of some 50,000 men and women who were in their late eighties in 1959 and were traced to the end of 1979 . The ages of these subjects were repeatedly examined, so that the death rates derived for ages 95 and older in this study are probably more accurate than those in the medicare experience. These death rates also corroborate John Wilkin's point that population mortality flattens out in the late 90 s ; at age 95-105 the death rates in the American Cancer Society study ranged from 0.3 to 0.4 .

There is considerable difference of opinion regarding the reasons for the sharp reduction in death rates past age 65 , and especially past age 85 . Hence, there are also different views on the likelihood of further decreases in mortality in the near future. I believe that the decline in death rates since the mid-1960s reflects primarily such factors as rising living standards, the influence of medicare, greater general understanding of health hazards and more salutary life styles, as well as some specific improvements in medical treatment, notably that of hypertension. Death rates among Mormons and Seventh-Day Adventists and the studies conducted by the Human Laboratory group in Alameda County, California, illustrate well the potent effects of healthful habits.

If my appraisal of the influences affecting death rates during the last fifteen years is correct, then mortality should continue on a downward trend in the years immediately ahead.

The obvious merit of projecting mortality decreases into the future is exemplified by the table at the top of page 743, which compares values at 5 percent on the Annuity Table for 1979 and the 1983 Table $a$.

In 1949, W. A. Jenkins and I developed the Annuity Table for 1979 (TSA, I, 369) to represent the approximate level of annuitant mortality in 1979 on reasonable assumptions as to future declines in mortality. In my judgment, any reasonable assumptions would have produced sensible values. However, the recent sharp reductions in death rates at the older ages suggest different projections for the years ahead.

|  | Annuity Table for 1979 |  | 1983 Table $a$ |  | Percent Values on the Annuity Table for 1979 to Those on 1983 Table $a$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Males | Females | Males | Females | Males | Females |
| 35 | 17.176 | 17.745 | 17.134 | 17.793 | 100.2\% | 99,7\% |
| 45 | 15.570 | 16.438 | 15.620 | 16.569 | 99.7 | 99.2 |
| 55 | 13.353 | 14.465 | 13.610 | 14.772 | 98.2 | 97.9 |
| 65 | 10.874 | 11.625 | 10.918 | 12.262 | 99.6 | 94.8 |
| 75 | 7.681 | 8.019 | 7.775 | 9.016 | 98.8 | 88.9 |

JOHN O. MONTGOMERY:
The 1983 Table $a$ will be presented to the NAIC at its December, 1981, meeting for disclosure and will be presented for adoption by the NAIC, along with guidelines for implementing its promulgation by the various states, at the June, 1982, meeting of the NAIC. This disclosure period conforms with established NAIC procedures for adopting experience tables. At that time all states which will have passed the new 1980 amendments to the valuation and nonforfeiture laws will be able to incorporate this table by regulation. To date, seventeen states have enacted these laws. We expect that by 1982 another seventeen to twenty states will have enacted these laws. Therefore a majority of the states will be able to use this table next year.

The question I have is whether or not you attempted to use the so-called log-linear method that was used in the construction of the new disability tables. This method has the capability of translating almost any table of experience values into a relatively simple mathematical formula. I do not think it likely that you have, since the report of the committee to construct the disability tables has yet to be published. At some future time it may be worthwhile to see whether the annuity tables can be so transformed using the log-linear method that was used in the disability tables.

## COMMITTEE'S REVIEW OF DISCUSSION:

The exposure draft of the report of the committee was mailed to members shortly before the Society's 1981 annual meeting, and the draft was presented and discussed at that meeting. A covering letter from President Leckie invited comments from the membership to be sent to the committee chairman by November 6, 1981. Recognizing the short period for review, the committee considered comments received after that date, as well. All comments are discussed in this review whether or not they have been published as discussions. It should be noted that the final published report has, in several places, been changed from the exposure draft as a result of suggestions in the discussions.

Mr. Edward A. Lew's remarks were most kind and gracious. The committee wishes to express its gratitude and appreciation to Mr. Lew for his comments, especially considering that his landmark paper with Wilmer A. Jenkins, "A New Mortality Basis for Annuities" (TSA, 1, 369), set a scholarly standard for future authors to aim at. Additionally, his discussion of mortality at the extreme old ages and his review of reasons for the recent and continuing reduction in mortality rates add considerably to the value of the report and to a better understanding of the committee's conclusions. We shall look forward to Mr. Lew's presentation of the high-age mortality experience when he feels it can be published, a date we hope is earlier rather than later.

The committee is also grateful to Mr. John C. Wilkin who, in the oral presentation of his paper, "Recent Trends in the Mortality of the Aged," at the 1981 annual meeting, stated, in part, "We concur with (the) committee's recommendation that at this time we need to project significantly higher rates of improvement in mortality, particularly at the older ages." We also noted with some satisfaction Professor William H. Wetterstrand's comment in a letter to the committee that his "analyses of medicare data lend considerable support to the use of 1.5-2 percent projection factors in an annuity table for ages $30-90$,' using the methods described in his paper.

Mr. John Tomlinson questioned the committee's use of a single set of improvement factors for the period from 1973 to 1983, while for the period beyond 1983, separate male and female improvement factors were suggested. The reasons given in the paper for deciding on only a single set of factors for the period 1973-83 do, in fact, describe the basis for the committee's decision. The reasoning of the committee was somewhat as follows.

Preliminary sets of 1973-1983 improvement factors had been prepared for males and females separately for ages over 30 . These two sets appear in Table 1 of this discussion. The improvement rate for males aged 30-34 through $40-45$ was then reduced from 2.5 to 2.25 percent. The committee also felt that improvement factors in excess of 2.5 percent were unduly high for females. After these changes were taken into account, the differences between the separate male and female factors would have been rather small, too small in the opinion of the committee, considering the variation in improvement rates from various sources, to warrant two separate scales.

In addition, the period from 1973 to 1983 was relatively short, and it was felt that enough of the 1973-83 period had already transpired that it was unlikely that there would be any marked changes in the years remaining. For the longer-range period, beyond 1983, it seemed appropriate to recognize the historically greater improvement rates among females, a rec-

TABLE 1
Mortality Improvement Rates

|  | Preliminary |  |  | Modified Female Improvement Rates | FinalImprovementRates |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | Male | Female | $\begin{aligned} & \text { Excess } \\ & (\mathbf{F}-\mathbf{M}) \end{aligned}$ |  |  |
| 32 | 2.5 \% | 2.0 \% | -0.5 | 2.0 \% | 1.00\% |
| 37 | 2.5 | 2.25 | -0.25 | 2.25 | 2.25 |
| 42 | 2.5 | 2.5 | 0 | 2.5 | 2.25 |
| 47 | 2.25 | 2.75 | 0.5 | 2.5 | 2.25 |
| 52 | 2.25 | 3.0 | 0.75 | 2.5 | 2.25 |
| 57 | 2.25 | 3.0 | 0.75 | 2.5 | 2.25 |
| 62 | 2.25 | 3.0 | 0.75 | 2.5 | 2.25 |
| 67 | 2.25 | 3.0 | 0.75 | 2.5 | 2.25 |
| 72 | 2.25 | 2.75 | 0.5 | 2.5 | 2.25 |
| 77 | 2.0 | 2.50 | 0.5 | 2.5 | 2.00 |
| 82 | 1.75 | 2.25 | 0.5 | 2.25 | 1.75 |
| 87 | 1.5 | 2.0 | 0.5 | 2.0 | 1.50 |
| 92 | 1.5 | 1.75 | 0.25 | 1.75 | 1.50 |
| 97 | 1.5 | 1.5 | 0 | 1.5 | 1.50 |

ognition which was consistent with the commentaries that had been reviewed and summarized in the report and on which Projection Scale $G$ was largely based.
Mr. Tomlinson also provided the committee with an extensive and detailed set of editorial changes, questions pertaining to clarity and suggestions of areas for improvement in presentation. The committee appreciates his painstaking work and has adopted or acted on most of his suggestions. We think that the final version of the paper has been considerably improved over the exposure draft in readability and clarity because of his efforts.
Mr. John H. Cook's extensive discussion of mortality at ages 85 and over adds considerable value to the committee's report. As he and Mr. Wilkin noted, the greater numbers of people surviving to these advanced ages will make the financial effects of lower mortality more important to both annuity valuation and social security costs. The comparisons in Table 11 of the report were intended to indicate that the 1983 Table $a$ mortality rates were not markedly low when compared to recent experience. To learn that projected aggregate annuity mortality is higher than some actual insured life ultimate experience is somewhat disturbing. However, not only was the ultimate experience restricted to issues of 1960 and later, but the strict underwriting mentioned by Mr. Cook was indeed very restrictive, and the policies involved were those in the higher-amount second and third tiers of a three-tier classification system. All three of these factors would assure a more select group. The experience should perhaps be viewed as an indi-
cation of the possible effect of annuitant selection on mortality at very high ages. The committee thanks Mr. Cook for his contribution and suggests that Mr. Lew, Mr. Wilkin, Mr. Cook, and others pursue further study of mortality levels and changes at high ages.

A possible counterbalancing force affecting future changes in annuitant mortality has been cited in Mr. James Cowen's discussion. Certainly inclusion of terminated pension plans in the experiences on immediate annuities and on matured deferred annuities should tend to offset the lower mortality of individual purchasers of annuities. The magnitude of the effect will, of course, depend on the relative size of the terminated pension business. It would be interesting and useful to check for this effect in the next intercompany annuity mortality study.

Mr. Cowen's theory on the cause of improved mortality at the high ages is very likely true. There appears to have been a synergistic effect of the combination of efficacy and availability of diagnosis and treatment, interest on the part of both patients and the medical profession, and the funds to pay the costs.

In a letter to the committee, Mr. Paul H. Jackson took issue with the committee's rejection of a merged-gender valuation table in favor of separate male and female valuation tables. Stating that the "conclusions reached cannot be justified on technical actuarial grounds," Mr. Jackson, referring to the committee's discussion on this point as originally presented in the exposure draft, wrote as follows:

The entire discussion relates to the extent to which a merged-gender table might develop inadequate reserves if the proportion of females to males should be greater than that assumed in the basic table. I can agree that a merged-gender table that is appropriate at issue might, due to subsequent deviation of percentage female from that assumed, become inappropriate or even unsafe. . . . My problem . . . is that I view the difference between male and female mortality in this area of setting reserves for annuities as far less significant than the matter of interest rates, and all of your arguments apply equally to the rate of return on invested assets initially and on into the future.

The report of the committee sets out male and female commutation functions at 5,7 , and 9 percent interest. Taking the 7 percent interest values as the middle rate, the variation in female annuity value to male annuity value runs about $1031 / 4$ percent at $40,1073 / 4$ percent at 60 , and $1123 / 4$ percent at 80 . Taking an average mix of business and assuming a $50 / 50$ unisex table for reserve purposes, the worst that could happen would be that the group could shift to 100 percent female, and this would involve about a $41 / 2$ percent increase in actual reserve liability over that developed by the unisex table. On the other hand, if the reserves were based on a 7 percent basis, a $41 / 2$ percent variation in the reserve liability on the sex-distinct table would result whenever the assets shifted in such a way as to develop an interest yield $1 / 2$ percent
different from the 7 percent assumed rate. There is no doubt in my mind but that the likelihood of a swing in the sex content of a company's annuity business from $50 / 50$ to $0 / 100$ or $100 / 0$ is far less than that of a swing in interest yields from 7 percent to $61 / 2$ or $71 / 2$ percent. Accordingly, from a purely scientific point of view, I believe that if you are going to raise hypothetical questions about the problems raised prospectively when the mix of business deviates from that assumed in the original unisex table, then in faimess you should make the similar argument about what happens to the adequacy of reserves when the asset mix shifts so that the prospective yield varies from the single rate used in the reserve table.

Finally, the basic argument that you have set out here is that an actuary, for reserve purposes, should not average male and female experience and use an overall average unisex valuation mortality table. On the other hand, you apparently condone, without comment, the fact that the actuary in 1981 who uses even a 9 percent valuation rate of interest for a block of new business could not possibly be suggesting that the money would be invested so as to yield only 9 percent next year. Many of the insurance companies that are issuing these annuity contracts and that will use the table for valuation purposes are currently offering guaranteed investment contracts with yields in the general neighborhood of 15 percent. This suggests that those actuaries are assuming a high rate of return in the early years and a lower rate of return in the later years, working out to some overall average single rate of return such as 5,7 , or 9 percent, and that average rate is deemed to be appropriate for reserve purposes.

If a company bases reserves on an average rate of 7 percent, which has been selected so as to reflect real-world yields of 15 percent in 1982 grading down to 5 percent in 10 or 15 years, then that company's block of reserves will develop experience gains in the early years which must be held as reserves to offset the experience losses of later years arising out of interest rates that are ultimately less than the 7 percent level. With select and ultimate interest as the basis for reserves, these amounts would indeed be included in the reserves. With a single interest rate as the basis for reserves, the additional interest in early years would show up as added surplus. Surely, on theoretical grounds this practice is no more to be condoned than the practice of approximating mortality rates by a unisex table.

My recommendation, quite simply, would be to delete the statement that "use of a merged-gender table for valuation is not recommended." Second, in the last paragraph, the statement that "the committee does not advocate use of a merged gender mortality table for valuation" should also be deleted. The committee should not be advocating anything.

I do recognize the difficulty that you have had in developing tables for valuation, and I certainly have no objection to your setting out separate male and female tables as the standard approach. I do strongly object, however, to your characterization of the unisex mortality table as unsound, when in fact you are clearly advocating another practice (the use of single interest rates) which is demonstrably even more unsound. There should be a substantial muting of the crusading tone in this section of your report. It is one thing to prefer to employ sex-distinct valuation mortality tables, but it is a far different matter to contend, as this section appears to, that the actuary
using a merged-gender table is somehow running tremendous risks. I believe that any actuary reviewing the figures dispassionately would conclude that the likelihood of having the percentage female rise from say, 50 percent to 60 percent is very much smaller than the likelihood of having the actual rate of return vary from the assumed rate by one-tenth of 1 percent, and yet the financial risk in these two situations is about the same.

Ms. Daphne D. Bartlett also wrote to the committee on this subject to "second Paul Jackson's request that some modification be made . . . in the section on sex-distinct tables.' She distinguished the actuary's right to price according to sex or other risk factors from the use of sex-distinct valuation tables. She also expressed concern that the committee's wording in the section on merged-gender tables implied that "use of this valuation table in combination with 'appropriate' interest rates will provide sufficient reserves'" (emphasis Ms. Bartlett's). Her primary concern appeared to be more with the language used in the committee's reasoning than with the committee's decision, as she pointed out that "minimum valuation reserves are necessary but may not be sufficient."

On the other hand, Mr. James Bagshaw, in a letter to the committee, strongly supported the "committee's decision not to advocate the use of merged-gender mortality tables for valuation purposes." Noting that "pressures that have been placed on our profession by the nondiscrimination laws of this country should not cloud our judgment as to the proper methods for determining the present value of future benefits to decidedly different classes of mortality risk,'" Mr. Bagshaw said that a merged-gender table for valuation would work only for certain types of groups over relatively short periods of time.

With respect to Mr. Jackson's comments, the committee wishes to make clear that it was not implying or stating any conclusion or recemmendation as to a choice of interest rates or the conviction that the proposed 1983 Table $a$ would provide sufficient reserves at some interest rate. In reviewing the reasons for constructing a new valuation mortality table, the committee cited "the concept of dynamic interest rates for valuation" as further eroding "interest rate margins available to cover inadequate or negative mortality margins." The committee suggested later in the report that a valuation actuary who believes that his company's "proportion of new, select annuity business is substantially higher than that in the experience used for the new table should make suitable adjustments." Similar action is suggested where a company has a high proportion of nonrefund immediate annuity business. Further, the committee provided values at various interest rates to permit comparison of the effect of changes in interest rates and mortality tables. In effect, the committee was careful to make no comment as to a choice
of an interest rate or the sufficiency of reserves on any table in any particular case. In fact, in the section discussing the 10 percent margin, the text notes that the 10 percent margin is not sufficient for all companies.

The committee disagrees with Mr. Jackson's contention that because of the considerable effect of different interest levels on reserves, a smaller error in reserves because of mortality is of no consequence. Rather, the committee, in recommending a new valuation table, recognizes the need to minimize variations to the extent that this can be done.

Both Mr. Jackson and Ms. Bartlett suggested that their arguments were more concerned with the way the case against a merged-gender table was presented than with the decision itself. Accordingly, the committee reviewed the exposure draft text and made extensive revisions, inserted a discussion of the inability of any single merged-gender table to be applicable to a variety of companies with differing proportions of males and females, and shortened the discussion on later effects of changes in the proportions of males and females as a block of business ages. The committee also made it clear in the revised text that the discussion and recommendation referred to the use of a merged-gender table as a valuation standard.

The committee is indebted to Ms. Bartlett and Messrs. Jackson and Bagshaw for their letters and their questioning of the committee's handling of this question. The values of their contributions can be seen in the substantially revised text in this section of the final report.

Mr. John Montgomery asked whether the committee had considered a log-linear formula approach of deriving a mathematical formula for the 1983 Table $a$. Since the Heligman-Pollard method seemed to offer considerable promise, the committee concentrated its efforts on adapting to that form. It did not consider any other approach, since the Heligman-Pollard approach also included the Makeham and Gompertz formulas, the heretofore standard formulas for mortality rates.

Mr. James Bagshaw and Mr. Albert Christians both objected to the exposure draft's format of the commutation columns, in which the number of significant figures was far exceeded and the number of decimal places at the younger ages became unwieldy. The committee had intended to follow the format of the commutation columns in Harold Cherry's paper on the 1971 IAM Table (TSA, XXIII, 475). However, the programmer was unable to solve the problem of proper rounding in time to meet necessary deadlines. The commutation columns in the final report are more amenable to calculation.

Mr. Christians raised the question of the definition of "attained age" in the 1971-76 annuity experience, that is, was it age nearest birthday, last birthday, or what? In TSA, 1973 Reports, page 61, the statement was made
that "the study is on an attained-age basis, where attained age equals age at issue plus contract year less one. The age at issue was taken as the age nearest birthday on the issue date of the contract, or some reasonable approximation to that age." Mr. Christians also asked that the committee include in Table 8 a tabulation of the 1971-76 experience showing exposures and deaths by five-year age groups, or preferably by single year of age, for both amounts of annual income and numbers of contracts. The committee believes it would not be cost effective for it to produce the data by single age or even in five-year age groups. The basic data appear in TSA, 1979 Reports, although the age grouping is by ten years of age.

The committee is most grateful to all who submitted discussions or letters on the exposure draft. It should be obvious from the foregoing that these discussions and letters played an important part in modifying the report and that they have unquestionably contributed considerably to its improvement.

# REPORT OF THE TECHNICAL ADVISORY COMMITTEE ON DYNAMIC INTEREST AND RELATED MATTERS 

To: The NAIC Actuarial Advisory Group

Subject: Annuity Valuation Mortality Tables
Date: December 12, 1981
The Technical Advisory Committee has reviewed the Exposure Draft on "Derivation of the 1983 Table $a$ for Individual Annuity Valuation" prepared by the Society of Actuaries Committee to Recommend a New Mortality Basis for Individual Annuity Valuation, chaired by Robert Johansen. It is the consensus of the Technical Advisory Committee that the Johansen Committee has done a superb job in the development of 1983 Table $a$ and preparation of this exposure draft, and we strongly endorse the recommendations set forth in the draft.
Specifically, we recommend that the NAIC adopt 1983 Table $a$ as a mortality table suitable for the valuation of annuity benefits under individual annuities and supplementary contracts issued in 1983 and subsequent years. Moreover, we recommend that this table be adopted by the NAIC as the minimum valuation standard mortality table for the valuation of such annuity benefits.
In particular, the Technical Advisory Committee supports the recommendations in the exposure draft as to the propriety of gender-distinct mortality rates for the valuation of annuity benefits and in any minimum valuation standard mortality table.
We recognize that while the 1983 Table $a$ mortality rates have margins that appear sufficient to provide for future mortality improvement affecting annuities issued in 1983 and even during the several years beyond 1983, we would expect that continuing improvements in mortality will make it necessary to replace the 1983 Table $a$ by a more conservative table in perhaps five years, applicable to annuities and supplementary contracts issued thereafter. At that time, the NAIC may choose to adopt as a new minimum valuation standard mortality table the 1983 Table $a$ with five years' projection using the exposure draft's Projection Scale G, or it may choose to adopt another table if warranted by actual mortality experience during the intervening years.
Again, the Technical Advisory Committee welcomes this opportunity to comment on the proposed individual annuity valuation mortality table. We want to commend the Johansen Committee on the outstanding work done by that group in developing the 1983 Table $a$, and on the excellent exposure draft.

Submitted for the Technical Advisory Committee
Charles Greeley, F.S.A., M.A.A.A.
Chairman
