# TRANSACTIONS OF SOCIETY OF ACTUARIES 1989 VOL. 41 

## A GUIDE TO QUANTIFYING C-3 RISK

JOHN A. MEREU

INTRODUCTION
The C-3 risk is the risk of loss faced by a financial intermediary, such as a life insurance company, because of changes in either the level of interest rates or the shape of the yield curve.

The term C-3 was coined by the Trowbridge Committee on Valuation and Related Matters, which noted in 1979 that the risks faced by insurance companies could usefully be classified as $\mathrm{C}-1$, the risk of asset failure; C 2 , the risk of pricing insufficiency; and C-3.

The $\mathrm{C}-3$ risk comprises the mismatch risk and the disintermediation risk. The mismatch risk, described by Redington [5], arises when there is a mismatch in timing between asset and liability cash flow streams, the consequences of which are either asset reinvestment or disinvestment transactions in an uncertain future interest rate environment. The disintermediation risk arises when options are available to either asset or liability clients that expose the intermediary to financial antiselection.

Actuarial literature of the last decade refers frequently to the C-3 risk, and much work has been done in the field of interest rate modeling. The purpose of this paper is to provide a guide to a practicing actuary in quantifying the $\mathrm{C}-3$ risk for a company or a block of business. This paper is designed primarily for valuation actuaries who must decide on interest rates for valuation purposes and for corporate actuaries who must decide on adequate surplus levels.

## OUTLINE OF A C-3 MODEL

Quantifying C-3 risk requires a model that can simulate the future cash flow for a block of business under different interest rate scenarios. Each simulation should proceed sequentially from interval to interval either until all liabilities have been discharged or until some earlier point in time when all assets have been exhausted. At each simulation date the assets and liabilities should be valued, the surplus position assessed, and a determination made of the initial additional asset required to avoid insolvency. A measure of the C-3 risk on a simulation is obtained by comparing the starting asset required to avoid a state of insolvency during the simulation to the initial imputed value of the liabilities. By performing the simulation under a number of different scenarios, the actuary obtains a probability distribution of the

C-3 risk and can make provision for it in either additional reserves or appropriated surplus at a desired confidence level.

The main ingredients of the $\mathrm{C}-3$ model illustrated in this paper are:

1. A model for generating plausible future interest rate scenarios
2. The liability cash flow vector
3. The asset cash flow vector
4. Logic for imputing values to flows
5. The reinvestment strategy to be applied when asset cash flow exceeds liability cash flow, generating excess assets for investment
6. The disinvestment strategy to be applied when liability cash flow exceeds asset cash flow, causing a cash shortage for meeting current obligations
7. Call logic to simulate cash flow changes arising as clients exercise options prompted by a drop in interest rates (Examples are bond calls and mortgage prepayments.)
8. Put logic to simulate cash flow changes arising as clients exercise options prompted by a rise in interest rates (Examples are cash surrenders and new policy loans).
In each simulation the logic proceeds sequentially from one interval to the next. The spacing of the intervals might be monthly, quarterly, or annually. For many purposes yearly intervals will be appropriate, but if the cash flow is highly seasonal, a yearly model may give a poor estimate of the C-3 risk. For the model illustrations in this paper simulation dates are yearly. At each simulation date the model first determines whether and to what extent call or put options are to be exercised and adjusts the asset and liability cash flows accordingly. The model then applies asset cash flow occurring at the simulation date to settle liability payments falling due at the simulation date. If at the simulation date the asset cash flow exceeds the liability flow, the excess asset flow is reinvested according to the reinvestment strategy. If at the simulation date the asset cash flow is less than the liability flow, the shortfall is met by the sale of future asset cash flow according to the disinvestment strategy. The results in either event are a reduction to zero at the simulation date of both the asset and the liability cash flow and appropriate changes in future asset cash flow.

Appendix 1 shows the asset and liability cash flow vectors and the initial valuation factors. The flows were arbitrarily created, and the initial valuation factors are derived from the initial yield curve. The Macaulay duration and convexity factors are shown as well; these indicate a significant degree of mismatch between the asset and liability flows in the illustration.

Although one hundred simulations were performed in the analysis, the $\mathrm{C}-3$ requirements of only ten of them are listed in the illustration. For these
ten simulations the C-3 requirements vary from $\$ 320$ to $\$ 49,520$. The mean C-3 requirement for the 100 simulations is $\$ 17,187$, or 2.7 percent of liabilities.

The C-3 requirements at different confidence levels, determined from a ranking of the results of all the simulations, are shown as well. For example, the C-3 requirement at the 50 percent confidence level is $\$ 13,375$ and at the 99 percent confidence level is $\$ 60,335$.

Shown as well are the valuation rates of interest if the reserves are intended to incorporate an amount to cover the $\mathrm{C}-3$ risk at a particular confidence level. These were obtained by solving for the internal rate of return with the present value of the liability flow set equal to the initial present value increased by the amount required to cover the $\mathrm{C}-3$ risk at the given confidence level.

Appendixes 2 and 3 show calculation details for two of the simulations. Simulation 10, which appears in Appendix 2, illustrates events on a decreasing track. Simulation 90, which appears in Appendix 3, illustrates events on an increasing track.

## INTEREST GENERATION MODEL

The interest generation model designed for this paper (referred to as IGM) is a stochastic model designed to generate a spectrum of plausible future inflation rate tracks, long-term (ten-year) interest rate tracks, and short-term (three-month) interest rate tracks. After the tracks were generated, they were ranked according to the sum of the long-term rates and short-term rates that were simulated. The result is that low-numbered tracks are associated with low-interest-rate simulations and high-numbered tracks are associated with high-interest-rate simulations. See Appendix 4 for statistical information on 100 simulated interest rate tracks. Appendixes 2 and 3 show full details on tracks 10 and 90 . See Appendix 5 for mathematical details.

## Inflation Rates

IGM assumes that interest rates are influenced by inflation rates. Inflation depends on global and national economic forces and, as recent history shows, can range over a wide spectrum. The model requires four parameters to simulate inflation: the starting rate, the maximum and minimum plausible rates of inflation, and the inflation drift component. In each simulation the model takes the inflation rate for a random walk with steps that are normally distributed with a mean of zero and a standard deviation equal to the drift
component, subject to the condition that the walk cannot go outside the minimum and maximum barriers.

## Long.Term Rates

IGM requires four parameters to simulate long-term interest rates: the starting rate, the long-term goal, the long-term trend component, and the long-term drift component. In each simulation the model takes the long-term interest rate for a random walk in which each step has two components. One component is stochastic and adds to the logarithm of the long-term rate a normally distributed random number with mean zero and standard deviation equal to the long-term drift component. The second component is deterministic and moves the long-term interest rate towards a moving target equal to the sum of the inflation rate and the long-term goal, the gap being closed by a fraction equal to the long-term trend component. The long-term rate might be likened to a drunk chasing a moving inflation rate.

## Short-Term Rates

IGM requires five parameters to simulate the ratio of short-term rates to long-term rates: the starting ratio, the ratio goal, the short-term trend component, the short-term drift component, and the maximum plausible ratio. In each simulation the model takes the ratio on a random walk in which each step has two components. One component is stochastic and adds to the logarithm of the ratio a normally distributed random number with mean zero and standard deviation equal to the short-term drift component. The second component is deterministic and moves the ratio towards the ratio goal, the gap being closed by a fraction equal to the short-term trend component. The process is modified to prevent the ratio from exceeding the maximum plausible ratio. The short-term rates are readily computed given the long-term rate and the ratio of the short-term rate to the long-term rate.

## Comment

Adding a random amount to the logarithm of a variable is equivalent to multiplying the variable by a positive random amount. Under such a process, the random variable never becomes negative, a desirable attribute when simulating interest rates.

## Yield Curves

By simulating the long-term rate (ten years) and the short-term rate (three months), one gets two points on the yield curve. Other points are required for the C-3 model. While a linear interpolation might be used, I found that a cubic curve gives a better representation of past yield curves, with parameters of the cubic curve determined by the spread between the three-month rate and the ten-year rate.

## Assignment of Parameters

To generate a set of plausible future-interest-rate scenarios, the parameters should be assigned in a credible manner. For the illustrations in this paper, a number of principles were followed in assigning parameters.

For past-interest-rate data, the Report on Canadian Economic Statistics [1] was used.

The starting values of the inflation rate, the long-term rate, and the shortterm rate are those for 1987. The maximum inflation rate of 15 percent reflects a belief that the government can prevent and will not tolerate a higher rate. The long-term goal of 4 percent reflects the belief that the real rate of interest adjusted for inflation is relatively stable and in the 3-4 percent range. The minimum inflation rate of minus 4 percent recognizes the occurrence of negative inflation rates in the past and sets a floor for the long-term rate of 0 percent. The short-term ratio goal was set at 0.726 to reflect the average historical ratio. The short-term ratio maximum was set at 1.3 , because higher ratios appear implausible.

The trend and drift factors were derived by using a trial-and-error process on past data. The drift component for each past year can be imputed if the trend and goals are stipulated. The experiment was repeated for different stipulations until a drift component with zero mean was obtained.

## Comments on Interest Models

Much of the recent literature on interest rate modeling deals with binomial and diffusion models. These are more sophisticated than the type of interest rate simulation described above and are geared more to the needs of an investment actuary responsible for asset-liability matching. A good survey of interest rate models has been prepared by Sharp [6].

## THE LIABILITY CASH FLOW VECTOR

The liability cash flow vector is the net expected cash outflow by interval for benefits, expenses, and premiums. The elements of the vector may be positive or negative, but the general thrust will be positive. Negative liability flow is equivalent to positive asset flow. The liability cash flow must be determined by the actuary from an analysis of the block of business with appropriate assumptions for mortality, lapses, expenses, and so on.

## THE ASSET CASH FLOW VECTOR

The asset cash flow vector is the net expected cash inflow by interval for the assets supporting the block of business. The asset cash flow must be determined by an analysis of the underlying assets. Each bond and mortgage in the portfolio can be depicted as a cash flow stream ending at its maturity. For equity-type assets the cash flow stream may reflect both expected income while the asset is held and expected proceeds on future sale.

## LOGIC FOR IMPUTING VALUES TO CASH FLOWS

At any time the marketplace defines a market value for risk-free investments maturing at different future dates. From this information the yield curve then prevailing can be established. This principle has been well enunciated by Milgrom [3].

From the yield curve, valuation factors can be derived for determining the present value of future payments. The imputed value of the assets is derived by applying the valuation factors to the asset flow, and the imputed value of the liabilities is derived by applying the same valuation factors to the liability flow.

For the illustrations in this paper the initial yield curve applicable at the beginning of each simulation ranges from an effective yearly rate of 10.31 percent for a three-month horizon to 10.52 percent for a ten-year horizon.

The valuation factors derived from the initial yield curve are shown in Appendix 1. As the yield curve changes, the valuation factors change accordingly. For the detailed calculations shown in Appendixes 2 and 3, tables of the valuation factors at each simulation date are shown.

An advantage of using imputed values for the C-3 analysis is consistency in the valuation of both asset and liability cash flows. The imputed value of the assets is likely to be higher than the market values because the marketplace recognizes the value of options available to clients and any inherent C-1 risk.

If a block of business is in a surplus position, the imputed value of the assets should exceed the imputed value of the liabilities; the reverse is true of a block of business in a deficit position. In the illustrations in this paper, the imputed values of the assets and liabilities are equal to $\$ 643,394$ at the start of the simulation, implying a block of business initially in a neutral position.

## REINVESTMENT STRATEGY

At simulation dates when asset cash flow exceeds liability cash flow, the net amount must be reinvested. The model should reflect the company's reinvestment strategy. In the illustrations excess asset cash flow is invested in pure discount bonds maturing at the earliest dates when anticipated cash flow is negative. The price of such bonds is determined from the yield curve simulated to be in effect on the date of the excess cash flow.

## DISINVESTMENT STRATEGY

At simulation dates when asset cash flow is less than liability cash flow, there is a need to sell assets to meet current cash requirements. In the illustrations the assets to be sold are selected from those maturing at the earliest dates when excess cash flow is anticipated. The proceeds for such bonds are determined from the yield curve simulated to be in effect on the date of the cash shortage.

## CALL LOGIC

When interest rates fall, borrowers have a financial incentive to prepay their loans and to refinance them at the more favorable rates then prevailing. In doing so, they purchase for its call value an asset with an enhanced current value. In the illustrations the fraction of an asset that is called depends on the excess of its current imputed value over its call value and on two parameters: the call threshold parameter and the call intensity parameter. The call threshold parameter is the minimum differential that must exist before call activity commences, and the call intensity parameter recognizes the magnitude of reponse to a particular differential. The mathematical expression for the call fraction is given in Appendix 5. Setting the call parameters is likely to be subjective and should be done with investment department expertise, taking into account the availability of the call options and the predisposition of the asset clients to use them.

While call options tend to be associated with asset clients, there are situations in which they become available to liability clients. An example
occurs when liability clients have the right to make additional voluntary deposits at a guaranteed interest rate.

In the illustrations the call fraction is computed independently for the assets maturing at each future date. Call values were computed as 105 percent (the call penalty parameter) of the discounted value of the liability cash flow at 10 percent (the call interest parameter). The call values for reinvested assets are computed with the same call penalty parameter, but the call interest parameter is replaced by the interest rates current at the time of reinvestment. The parameters to be assigned by the actuary should be appropriate for the block of business being analyzed.

## PUT LOGIC

When interest rates rise, policyholders have a financial incentive to surrender policies or to borrow on their security. In doing so they sell at a favorable price future cash flow that has diminished in value. In the illustrations the fraction of the liability flow that is surrendered depends on the excess of the cash surrender value over its current imputed value and on two parameters: the put threshold parameter and the put intensity parameter. The put threshold parameter is the minimum differential that must exist before put activity commences, and the put intensity parameter recognizes the magnitude of reponse to a particular differential. The mathematical expression for the put fraction is given in Appendix 5. Setting the put parameters is likely to be subjective and should take into account the predisposition of policyholders to respond to interest rate changes.

For the illustrations cash values were computed as 95 percent (the put penalty parameter) of the discounted value of the liability cash flow stream at 6 percent (the put interest parameter). The parameters should be appropriate to the block of business being analyzed.

## REFERENCE TO OPTION PRICING THEORY

In referring to calls and puts, the above sections employ some of the language of option pricing theory, but the theory itself is not used. The presence of inertia in the exercise of prepayment, loan, and surrender options makes the application of option pricing theory in an insurance setting difficult for the problem addressed in this paper. Clancy has provided a good description of option pricing theory and its applications [2].

## CONCLUSION

The model described in this paper is designed to help an actuary analyze and quantify $\mathrm{C}-3$ risk. A critical ingredient in the process is an interest generation model that can generate a spectrum of plausible future yield curves changing through time in both level and shape. Some sensitivity analysis can be performed by using a set of postulated interest rate tracks, but such an approach has limitations if answers are desired at specified confidence levels.

## APPENDIX 5

## TECHNICAL DETAILS

## Normally Distributed Random Numbers

Given $R 1$ and $R 2$, two uniformly distributed independent tandom variates on the $(0,1)$ interval, then

$$
\begin{aligned}
& X_{1}=\left(-2 \ln R_{1}\right)^{1 / 2} \cdot \cos 2 \pi R_{2} \\
& X_{2}=\left(-2 \ln R_{1}\right)^{1 / 2} \cdot \sin 2 \pi R_{2}
\end{aligned}
$$

are two random variates from a standard normal distribution [4].

## Inflation Rate

Given the maximum inflation rate INFMAX, the minimum inflation rate INFMIN, and the inflation drift factor INFDRIFT, inflation rates INF are determined recursively as follows, starting with INFSTART at time 0 :

$$
\begin{gathered}
A=\operatorname{INF}(t-1)+(\text { INFDRIFT })(\text { NRN }) \\
\operatorname{INF}(t)=\operatorname{Max}[\text { INFMIN, } \operatorname{Min}[A, \text { INFMAX }]
\end{gathered}
$$

where NRN is a normally distributed random number with mean zero and unit variance.

Long-Term Interest Rate (10 year)
Given the long-term trend factor LTREND, the long-term drift factor LDRIFT, and the long-term goal LGOAL, the long-term interest rates are determined recursively as follows, starting with LSTART at time 0:

$$
\begin{gathered}
B=\operatorname{LINT}(t-1) \cdot \exp (\operatorname{LDRIFT})(\mathrm{NRN}) \\
\operatorname{LINT}(t)=B+\operatorname{LTREND}[\operatorname{LGOAL}+\operatorname{INF}(t)-\mathrm{B}]
\end{gathered}
$$

## Ratio of Short-Term Interest Rate (3 months) to Long-Term Rate

Given the short-term trend factor STREND, the short-term drift factor SDRIFT, the short-term ratio goal SGOAL, and the maximum plausible ratio RMAX, the ratios of the short-term rates to the long-term rates are
determined recursively as follows, starting with the initial ratio RSTART at time 0 :

$$
\begin{gathered}
C=\operatorname{RINT}(t-1) \cdot \exp [\operatorname{SDRIFT}] \cdot[\mathrm{NRN}] \\
\operatorname{RINT}(t)=\operatorname{Min}[\operatorname{RMAX}, C+\operatorname{STREND}(\mathrm{SGOAL}-C)]
\end{gathered}
$$

The short-term interest rates are then determined as follows:

$$
\operatorname{SINT}(t)=\operatorname{RINT}(t) \cdot \operatorname{LINT}(t)
$$

## Computation of Intermediate Yield Rates

Given the three-month rate and the ten-year rate at a point in time, intermediate rates $I(x)$ are obtained by a cubic interpolation given that $D$ is the excess of the ten-year rate over the three-month rate. First, a linear interpolation is performed:

$$
J(x)=I(0.25)+(x-0.25) \times \mathrm{D}
$$

Then

$$
I(x)=J(x)+(x-0.25)(x-10)(a x+b)
$$

where $a$ and $b$ are linear functions of $D$ given by:

$$
\begin{gathered}
a=0.002501+0.003611(D-1.1606) \\
b=-[0.021536+0.03563(D-1.1606)]
\end{gathered}
$$

The equations and parameters were derived from historical data that indicated that $a$ and $b$ were highly correlated with $D$.

In the absence of data, rates for terms longer than ten years are assumed to equal the ten-year rate.

## CALL Logic

CALL activity is invoked separately for each future asset payment if interest rates have dropped sufficiently. Let VN be the discounted value of the payment on the current yield curve and let VO be the computed call value. Let CMIN be the call threshold factor and CI be the call intensity factor. The fraction $F 1$ of the asset that is redeemed for its call value is given by:

$$
F 1=1-\exp -\mathrm{CI}[\operatorname{Max}(0,(\mathrm{VN} / \mathrm{VO})-\mathrm{CMIN})]
$$

## PUT Logic

PUT activity is invoked collectively for future liability payments if interest rates have increased sufficiently. Let VN be the discounted value of the liability flow on the current yield curve and let VO be the computed cash value. Let PMIN be the put threshold factor and PI be the put intensity factor. The fraction $F 2$ of the liabilities that are surrendered is given by:

$$
F 2=1-\exp -\operatorname{Pl}[\operatorname{Max}(0,(\mathrm{VO} / \mathrm{VN})-\mathrm{PMIN})]
$$

## DISCUSSION OF PRECEDING PAPER

FRANK J. ALPERT:

Mr. Mereu is to be congratulated for preparing an instructive and helpful paper about evaluating $\mathrm{C}-3$ risk. The investigation is becoming increasingly important, not only because of the magnitude of the potential losses and the difficulty of analysis but also because it is a central paradigm for other broad issues of management. I recommend the paper to both product actuaries and investment managers, as well as to corporate and valuation actuaries, because the decisions of the first groups will largely determine the extent of the risk.

Mr. Mereu has succinctly illustrated the elements that are essential for measuring $\mathrm{C}-3$ risk:

- An objective measurement of the risk at each checkpoint, translated into capital or reserve requirements, derived from
- Cash-flow testing, through
- Multiple economic scenarios, recognizing
- Investment and disinvestment strategies and
- Options available to asset clients; and
- Company pricing strategies and
- Options available to liability clients.

All these except company pricing strategies are explicitly used in Mr . Mereu's paper, and we can assume that pricing strategies are implicitly involved in the PUT parameters used in the calculations.

The testing discussed in the paper involves arbitrary asset and liability cash flows, in which the incidence of payments is considerably less wellbehaved than the typical block of insurance policies. This permits the reader to concentrate on the process rather than the product. But because the cash flows are arbitrary and there is an implied need for rebalancing each year, some of the relationships are less than obvious.

Mr . Mereu illustrates the $\mathrm{C}-3$ risk as a risk of cash-flow mismatch and measures it by comparing the present values of the asset and liability cashflow streams discounted at consistent interest rates. For the reasons outlined below, I prefer looking at year-by-year results.

The risk event we are trying to capture is the single interval (or separate intervals) in which the asset cash flow is less than the liability cash flow. If that occurs, the company will have losses and may have to supply capital to meet its obligations. The losses are real-there would be a real reduction
in economic value-but they may not show up immediately in accounting figures.

On the other hand, if the asset cash flow exceeds the liability cash flow in every interval in the scenario, then the company will show profits and will have no need for additional capital, and the present value of the net cash flow will always be positive. Conversely, a negative net present value signals that one or more future intervals will have negative cash flow.

In addition, other advantages of looking at single years rather than present values are as follows:

- The net present value can be positive and still have intervals with negative cash flows.
- A single-year measure can be coupled with a risk measure of solvency, requiring that the assets be bigger than the reserves on a year-by-year basis.
- In some models, today's present values can be obtained easily, but present values at future dates are difficult to obtain without a significant increase in running time.
For management use, the results of the scenario testing are summarized by degree of capital and remaining risk, as shown in the table below. This provides substantial information in a compact and understandable form.

Hypothetical SPDA

| Capital <br> As Percentage of Premium | ROE | Percentage of Years with Positive |  |
| :---: | :---: | :---: | :---: |
|  |  | Casth Flow | Solvency |
| 3 | 17.0\% | 73.7\% | 79.5\% |
| 5 | 13.3 | 80.0 | 88.9 |
| 10 | 10.0 | 86.0 | 98.7 |
| 15 | 8.7 | 88.1 | 100.0 |

As shown in the Appendix, the two procedures are equivalent and provide equivalent judgments under the assumption that at the valuation date the cash flows will be rebalanced.

Nevertheless, I recognize that actuaries are comfortable using present values and will continue to discount cash-flow streams, partly because discounted cash flow comes up in so many other contexts. For example:

- The present value of future profits is demonstrably equal to the present value of future net cash flows.
- The economic value of the enterprise can be defined as the present value of future profits. For stock companies, at least, this is the function that management should be striving to maximize.
- The market value of the assets is by definition the present value of the expected cash flow, discounted at current market interest rates. The corollary is that maximizing market value will enhance the economic value of the enterprise, because it will increase the present value of asset cash flows and net cash flows. Thus, it appropriate to manage the assets for total return within the established constraints.
- Many companies use duration measures as an operating rule. The underlying justification is that duration is a first approximation to the change in present value of a cash-flow stream when interest rates change; therefore, keeping asset durations close to liability durations will minimize changes in the net present value of assets less liabilities.
Perhaps the moral is that we seek statistics on single years, but plan profits on present values.

## Multiple Interest Rate Scenarios

Like Mr. Mereu, we use multiple, randomly generated, interest rate scenarios. I think this is the best approach. I agree that deterministic scenarios are limited if the actuary is interested in results at various confidence levels. Moreover, a deterministic set may not display all the risky scenarios. It could be said that every adverse event in economic history was a surprise at the time it happened.

Others who are much more expert in economics than I am have written extensively about how to randomly generate yield curves and interest rate scenarios. There are recommended assumptions for starting points, volatility and drift; there are recommended distributions; and sometimes it is required that there be no risk-free arbitrage. All these points are important.

I would just add two other observations: Whatever method is used, the actuary should review the resulting scenarios for reasonableness and economic sense; and depending on the purpose of the testing, the actuary may want to include differentials in other economic parameters on some random or distributed basis. In particular, the default rates and inflation should vary with the scenario conditions.

The necessity of review was brought out in a recent study we did. Great care had been taken in setting the initial rates, the shape of the yield curve, the probability distribution of short-term and long-term rates, the probability
of inversion, and the overall minimum and maximum rates. Nevertheless, on detailed examination about 30 percent of the scenarios were discarded because they were economically inconsistent. It is noteworthy that the rejected scenarios did not significantly affect the year-by-year means or variances of the overall set-they were found only by a computerized review of each scenario year by year.

The use of multiple year-by-year scenarios provides the opportunity to vary other economic parameters at the same time. For example, inflation rates should vary with interest rates. Depending on the purpose of the test, inflation could be directly derived from the Treasury rate in a deterministic approach or randomly related to the Treasury rate to more accurately reflect reality.

## Default Risk

Buff and others have demonstrated that the C-1 risk of loss of asset value must be considered in direct connection with the $\mathrm{C}-3$ interest rate risk. Accordingly, the same multiple scenarios that are used to test the C-3 risk should also be used to test the $\mathrm{C}-1$ risk. The initial default rate for each asset obviously depends on its quality rating. But from there, the default rates should change with the interest rates in the scenario, with more than linear increases for both high interest rates and lower quality. In our studies, we have used an exponential formula of the form

$$
\begin{aligned}
x & =\text { excess of } 90 \text {-day T-bill rate over } 71 / 2 \% \\
\text { Default } & =\text { Base Rate } \times K^{x}
\end{aligned}
$$

The factors and adjusted default rates produced by this formula are shown below:

|  | Investment Grade |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | A 2 | A | Baa | B |
| Factor $K$ | 1.05 | 1.09 | 1.125 | 1.125 |
| Base Default Rate at $7.5 \%$ or less | 0.0015 | 0.0017 | 0.0020 | 0.0250 |
| Default Rate at | 0.0017 | 0.0021 | 0.0027 | 0.0336 |
| 121/2\% | 0.0019 | 0.0026 | 0.0036 | 0.0451 |
| 15\% | 0.0022 | 0.0032 | 0.0048 | 0.0605 |

## Other Risks

Scenario testing can also be used to measure the effect of $\mathrm{C}-2$ risks such as increased mortality or lapse. This can be advantageous in producing a combined measure of risk in a single evaluation, rather than constructing separate studies.

## Asset and Liability Options

The two scenarios illustrated in the paper allow the reader to follow the logic of the calculations. The examples have either liability put options or asset call options, but not both at the same time. In real life, we can expect both options to be exercised at the same time in at least some circum-stances-one example would be deferred annuities with a bailout provision: A drop in interest rates would allow both the assets to be called and the annuities to be surrendered without penalty.

A model that allows both types of options to be exercised at the same time probably must include assumptions on the order of processing or allow for an iterative evaluation at each interval, or both. In any event, the actuary evaluating the $\mathrm{C}-3$ risk should be aware of how the structure of the model may affect the results.

## Summary

This excellent paper can be a guide for anyone interested in evaluating the C-3 risk. It succinctly illustrates the important elements and suggests ways of performing the calculations and displaying the results. I have made additional suggestions about the use of year-by-year results, the necessity of reviewing randomly generated scenarios, and a technique for simultaneous testing of the $\mathrm{C}-1$ risk by adjusting the default rates.

For those who are interested in further explorations within Mr. Mereu's model, additional tables and analyses are available at my Yearbook address.

## APPENDIX

Let $\operatorname{disc}(n, n+t)=$ the discount factor between $n$ and $n+t$.
\$1 at $n+t=\operatorname{disc}(n, n+t)$ at $n$
$\mathrm{ACF}(r)=$ asset cash flow at $r$
$\mathrm{LCF}(r)=$ liability cash flow at $r$
$\operatorname{PVACF}(s)=\Sigma \operatorname{ACF}(s+j) \times \operatorname{disc}(s, s+j)$
$\operatorname{PVLCF}(s)=\Sigma \operatorname{LCF}(s+j) \times \operatorname{disc}(s, s+j)$.

Assume:
the evaluation is at the end of interval $n$
$\operatorname{PVACF}(n)<\operatorname{PVLCF}(n)$ (otherwise there is no risk)
all $\operatorname{ACF}(r)=\operatorname{LCF}(r)$ except $\operatorname{ACF}(n+t)<\operatorname{LCF}(n+t)$
(the portfolio has been rebalanced to meet the liability cash flows to the extent possible).

In the paper, the $\mathrm{C}-3$ risk is measured by:

```
\(\operatorname{disc}(0, n) \times[\operatorname{PVACF}(n)-\operatorname{PVLCF}(n)]\)
    \(=\operatorname{disc}(0, n) \times[\operatorname{ACF}(n+t)-\operatorname{LCF}(n+t)] \times \operatorname{disc}(n, n+t)\)
```

since all other years drop out

$$
=[\operatorname{ACF}(n+t)-\operatorname{LCF}(n+t)] \times \operatorname{disc}^{*}(0, n+t)
$$

where disc* is a composite discount factor from the initial yield curve and the yield curve at time $n$. This differs from the calculation of the present value of the single year only in the discount rate:

$$
[\operatorname{ACF}(n+t)-\operatorname{LCF}(N+t)] \times \operatorname{disc}(0, n+t) .
$$

In theory, discounting should be at the successive rates used in the scenario, so that the value at $t=0$ would be:

$$
[\operatorname{ACF}(n+t)-\operatorname{LCF}(n+t)] \times \operatorname{disc}(0,1) \times \operatorname{disc}(1,2) \times \operatorname{disc}(2,3) \ldots .
$$

## SARAH L. CHRISTIANSEN:

Professor Mereu is to be complimented for writing such a readable paper on a current topic of great importance. It could serve as a basic guide to many actuaries. He clearly put a great deal of effort into his model, which is based on Canadian data. However, I have a few comments with respect to the model, most of which pertain to his interest-rate-generating mechanism (IGM).

## Regulation 126 Requirements

In the U.S. much of the C-3 testing is done to satisfy New York Regulation 126 as well as to meet internal purposes. New York requires that projections be continued until the major portion of insurance cash flows is gone from the contractual obligation on the valuation date [Section 95.9(c)].

New York Regulation 126 sets various horizons depending on the product type, which may easily exceed 10 years for such products as single-premium
whole life insurance. For annuities in payment New York Regulation 126 Section 95.9 suggests a time horizon of 20 years or longer.

Thus, it is important that:

1. There be rates for times greater than 10 years. U.S. data suggest that rates for 15,20 , and 30 years are generally different from the 10 -year rate.
2. The IGM project reasonable scenarios for 20 or 30 years.

## Relationship to Inflation

Projected interest rates should be the rates that the company expects to earn on its assets. In general, this would include a spread over Treasuries. Rarely would the long-term rate be less than the inflation rate, especially by the significant amounts that Professor Mereu indicates in his Table 4B. It is even rarer historically for the short-term rate to be less than the inflation rate.

By using Mereu's Appendix 5 (Technical Details), more simulations of interest rate scenarios were run with both a 10 -year and a 30 -year projection period.

The following table summarizes the number of occurrences and the percentage of times that IGM produced rates that were less than inflation.

|  | Rates Less Than Inflation |  |
| :--- | :---: | :---: |
|  | 10-Ycar Projection Period | 30 -Ycar Projection Period |
| Number scenarios | $400(4000$ curves $)$ | $200(6000$ curves $)$ |
| Long-term rates | $366(9.15 \%)$ | $747(12.45 \%)$ |
| Short-term rates | $49(1.225 \%)$ | $475(7.92 \%)$ |
| Both | $31(0.78 \%)$ | $358(5.96 \%)$ |

These simulations lead to the conclusion that the process tends to get out of hand when extended beyond the 10 -year scope or, to use Professor Mereu's rather graphic description, the moving inflation rate gets away from the drunk.

## Bounds on Rates

A question of reasonableness is whether there should be a minimum value for the ratio of short- to long-term interest rates. U.S. data seem to indicate
that a ratio of 0.6 would serve as a reasonable minimum, and that in fact was used in the above calculations for the 30 -year projection period.

The question of when is an interest rate scenario reasonable can be answered in part by looking at the rates that it projects. For the U.S., I would consider that all rates could be between 3 percent and 25 percent. Political considerations are likely to prevent interest rates from exceeding 25 percent. The U.S. national debt and health care inflation are likely to continue to keep rates above 3 percent. Although Canada does not have a problem with the national debt, Canada does have pressure on the National Health Insurance; thus Canadian rates would also be unlikely to be less than 3 percent. Also, Canadian interest rates are subject to pressure from the exchange rate in an attempt to maintain parity with the U.S. dollar. Hence, Canadian interest rates tend to be higher rather than lower than the U.S. counterparts. The political pressures and a stable Canadian economy lead to the conclusion that 25 percent is a ceiling for Canadian rates. New York Regulation 126 in fact requires that rates be between 4 percent and 25 percent.

Professor Mereu's IGM procedure tends to produce rates that are both too high and too low. The following table is a summary of the typical results using 100 scenarios.

|  | Number of Scenarios with |  |
| :--- | :---: | :---: |
|  | 10-Year Projections | 30-Year Projections |
| Rates between $3 \%$ and | 55 | 31 |
| $25 \%$ | 40 | 53 |
| Rates below $3 \%$ | 5 | 16 |
| Rates above $25 \%$ | 0.67 | 0.59 |
| Minimum | 28.99 | 36.98 |
| Maximum | 0 | 0.6 |

Due to the greater variability of the short-term rates relative to the long-term rates, it is almost always the short-term rate for which the problem occurs. Unfortunately there tend to be long sequences of rates that are too low (and occasionally too high), so that a simple "take the maximum (minimum) after the rates are calculated" would tend to stick at the 3 percent ( 25 percent) level.

## Parameter Modifications

At the cost of moving away from historically determined parameters, the input parameters were changed. The goals were to keep a tighter rein on
inflation, reduce to about 1 percent the frequency of short-term rates that were less than inflation, to give more power to the mean reversionary process, and to produce more reasonable results.

Reasonable changes in the parameters accomplished all the goals except that of producing reasonable results. Using parameter changes alone, reasonable 30 -year scenarios resulted 50 percent to 60 percent of the time, which was an improvement, but not sufficient. In order to minimize the stickiness that arises from putting barriers on the rates, it was preferable to compare rates at each point rather than after the scenario was completed.

The following table shows parameter changes that were made while attempting to maintain reasonableness.

| Parameter | From | To | Comments |
| :---: | :---: | :---: | :---: |
| Maximum Inflation | 15\% | 12\% | U.S. data showed only 2 years with a rate between |
|  |  |  | $12 \%$ and $15 \%$ from 1926 to 1987 . U.S. data showed only 1 year between these two |
| Minimum Inflation | -4\% | $-2 \%$ | U.S. data showed only 1 year between these two values (and 4 years during the Great Depression |
| Long-Tcrm Trend | 0.073 | 0.33 | where inflation < $-2 \%$ ). Increase power of mean reversionary process. |
| Short-Term Trend | 0.144 | 0.35 | Prevent process from getting out of hand. |
| Long-Term Goal | 4\% | 5.5\% | These factors are intertwined. In order to keep |
| Ratio Goal | 0.729 | 0.85 | short-term rates above the minimum, the long-term |
| Minimum Ratio | - | 0.65 | goal times minimum ratio should be above the minimum rate. The ratio goal is the expected ratio. |
| Minimum Rate | - | 3\% |  |
| Maximum Rate | - | 25\% |  |

These parameter settings produced the following results relative to inflation.

| Projection period | ( |
| :--- | :--- |
| Number of scenarios | 30 years |
| Long-term rates less than inflation | $100(3000$ curves $)$ |
| Short-crm rates less than inflation | $20(0.97 \%)$ |
| Both less than inflation | $20(0.67 \%)$ |

The short-term drift parameter controls how rapidly or smoothly the shortterm ratio and rates will change and also affects the proportion of inverted curves. The higher the drift factor, the greater the proportion of inverted curves and the more violent the yearly changes and hence more stickiness at 3 percent.

Professor Mereu's method for determining intermediate rates produces positively shaped yield curves (nondecreasing), inverted curves (which contain a small bump and are not monotonically decreasing), and some bowed curves (where the curve is nearly level). These shapes are very nice; however, it would be desirable to have 20 -year rates. Because Professor Mereu commented in the discussion on Mr. Jetton's paper "Interest Rate Scenarios" [TSA XL (1988): 423-39], what would be his reaction to solving Mr. Jetton's formula for the 10 -year rate in terms of one-year and 20 -year rates and for the 20 -year rate in terms of 10 -year and one-year rates?

At the risk of belaboring the obvious, cash-flow projections should be done separately for each class of assets or liabilities with different payment patterns or put and call characteristics, and then summed. Within classes more accurate parameters could be determined because of a greater degree of homogeneity in behavior. Taken to its logical extreme, the most accurate (and time-consuming) projections would be done on a seriatim basis.

## Duration Calculations

Professor Mereu mentions and calculates Macauley duration and convexity but does not discuss their use or significance. Macauley duration is used as a proxy for the percentage change in the present value for a given change in interest rates. When the durations of the assets and liabilities are matched, their present value then would change by the same amount, "immunizing" the company against changes in interest rates. As such, the Macauley duration is used as a proxy for the normalized first derivative of present value with respect to interest. Convexity as usually used is a normalized proxy for the second derivative of present value with respect to interest. However, they are appropriate proxies only in the case that the cash flows are not interest-rate-sensitive.

Note that

$$
P V=\sum_{t} c_{t}(1+i)^{-t}
$$

and thus

$$
\frac{d P V}{d i}=\sum_{t}\left[\left(\frac{d c f_{t}}{d i}\right)(1+i)^{-t}+(-t) c f_{1}(1+i)^{-(t, i)}\right]
$$

by the product rule; that is,

$$
\frac{d P V}{d i}=\sum_{i}\left(\frac{d c f_{t}}{d i}\right)(1+i)^{-t}-(1+i)^{-1} \sum_{t} t c f_{t}(1+i)^{-t}
$$

and the usual definition of Macauley duration is

$$
\sum_{t} t c f_{t}(1+i)^{-t}
$$

which is a proxy for the

$$
\frac{d P V}{d i} P V
$$

only if the first term is 0 , which implies

$$
\frac{d c f_{i}}{d i}=0
$$

which is to say that the cash flows are not themselves interest-rate-sensitive.
Option pricing models calculate duration and convexity as normalized proxies for first and second derivatives by evaluating the present value at three interest rates, $i_{0}, i_{0}+\epsilon$, and $i_{0}-\epsilon$ for some fixed, small $\epsilon$ such as 0.50 . They use approximations to the two-term Taylor series expansion for $P V$ at $i_{\mathrm{o}}$, assuming that the remainder term is small enough to ignore. After solving the resulting 2 by 2 system of equations, the results are normalized.
[Taylor series $P V\left(i_{0}+x\right)$

$$
\left.=P V\left(i_{0}\right)+P V^{\prime}\left(i_{0}\right) x+(1 / 2) P V^{\prime \prime}\left(i_{\mathrm{o}}\right) x^{2}+(1 / 6) P V^{\prime \prime \prime}(\xi) x^{3}\right]
$$

where $\xi$ is between $i_{\mathrm{o}}$ and $i_{\mathrm{o}}+x$.
In the case in which the cash flows are not interest-rate-sensitive, both techniques give the same results (provided that $\epsilon$ is sufficiently small). However, in the case in which the cash flows are interest-rate-sensitive, actuaries may be deriving a false sense of security from having Macauley durations matched. Convexities in particular appear to differ widely between the two methods.

Professor Mereu's investment technique is to minimize negative cash flows at the earliest future time and is not an immunizing strategy. It would be helpful to know how both techniques compare with respect to the $\mathrm{C}-3$ reserve requirement and perhaps also with respect to return on investment.

In conclusion, Professor Mereu has presented us with a basic model to determine $\mathrm{C}-3$ reserve requirements, which can be customized to fit the needs of many actuaries.

## (AUTHOR'S REVIEW OF DISCUSSION)

JOHN A. MEREU:
I thank Frank Alpert and Sarah Christiansen very much for their excellent discussions, which I believe greatly enhance my paper.

Both of the discussants have constructed and tested the model discussed in the paper.

Mr. Alpert, an actuary experienced in the asset management field, has made a number of good observations on alternate ways of presenting results and recognition of other risks. He also has suggested culling out unreasonable interest scenarios.

He has carried out some interesting experiments with the model. He notes that there may still be a significant amount of C-3 risk, even if initial cash flows are matched, arising from the presence of call and put options.

He also notes that if the $\mathrm{C}-3$ requirement is added to the initial assets, a mysterious shortfall can still develop if the investment strategy for such excess asset is the same as for the other assets. The model essentially assumes that such excess assets are invested in a long-term instrument maturing at the termination of the contract.

Dr. Christiansen has suggested a number of ways for improving the interest rate model results. By adjusting the driving parameters, she has reduced the number of unreasonable scenarios that are generated.

I agree with her suggestion that a realistic extension of the model beyond 10 years would be desirable. I did not have ready access to the history of 20 -year rates. The history should be analyzed to determine how 20 -year rates compare to 10 -year rates and 3 -month rates.

In conclusion, I am happy to have provided a framework in which further improvements for measuring the $\mathrm{C}-3$ risk can be developed.
