

## A Proof of Lidstone's Theorem

Richard W. Ziock

University of Iowa

Symbols:

$P$  = Net annual premium

$i_t$  = Interest rate

$t^q$  = Mortality rate

$C_t$  = t-th year contribution to surplus

${}_tV$  = t-th year reserve

Unprimed symbols are based on assumed rates.

Primed symbols are based on experience rates

Assumptions: Level benefits, level premiums.

Two factor contribution or dividend formula:

$$({}_{t-1}V + P)(1 + i_t) - q_t(1 - {}_tV) = {}_tV \quad (1)$$

$$({}_{t-1}V + P)(1 + i_t^q) - q_t^q(1 - {}_tV) = {}_tV + C_t \quad (2)$$

$$({}_{t-1}V + P)(i_t^q - i_t) + (q_t^q - q_t)(1 - {}_tV) = C_t \quad (2) - (1)$$

If the policy dividend equals  $C_t$ , this is the unique method of paying dividends which leaves each year's reserve unchanged. This fact is clearly seen in formula (2) since there if  $C_t$  is paid out the ending reserve is  ${}_tV$ .

Policy Comparisons:

Consider:

A: Non-Par plan based on  $i'$  and  $q'$

B: Non-Par plan based on  $i$  and  $q$

B': Par plan with net premiums based on  $i$  and  $q$ , which experiences  $i'$  and  $q'$ , with two factor dividends paid. B' may be looked on

as a non-par level benefit, decreasing premium plan based on  $i'$  and  $q'$ .

Observations:

B' has larger reserves than A.

Note:(1) Both are non par and based on  $i'$  and  $q'$ .

(2) Decreasing premiums lead to larger reserves (e.g. single premiums)

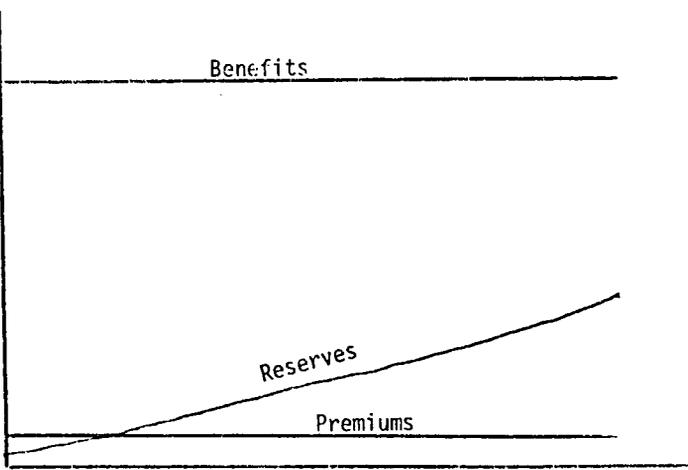

B' has same reserves as B because two factor dividends leave the reserves unchanged.

Thus B's reserves exceed A's or -

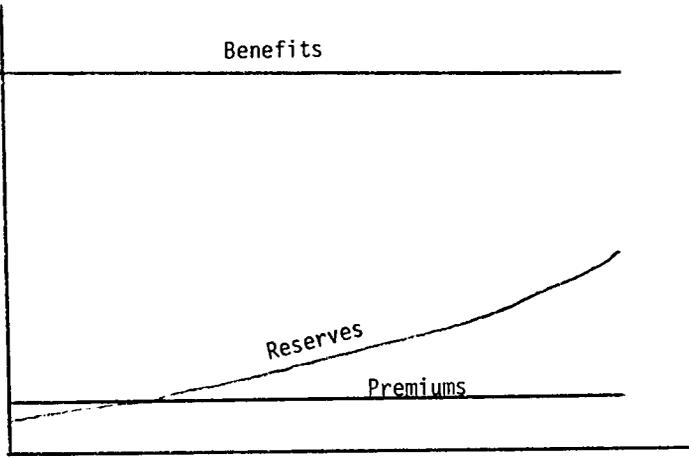

If  $C_t = ({}_{t-1}V + P)(i'_t - i_t) + ({}_tq - {}_tq')(1 - v_t)$  always increases the reserves based on  $i$  and  $q$  exceed those based on  $i'$  and  $q'$  and vice-versa.

This heuristic proof seems to be a little easier for students than the one in the Jordan text.
