# TRANSACTIONS OF SOCIETY OF ACTUARIES 1950 VOL. 2 NO. 3 

## ANNUITY MORTALITY

WALTER G. BOWERMAN

THe present notes include (a) extension to age zero of the 1949 tables by Messrs. Jenkins and Lew, (b) modifications at ages 10 to 29 male and 10 to 19 female required by the extension, (c) a lowering of the death rates at ages 89 and higher so as not to exceed population and insured life mortality for the same period of time, (d) modifications at ages $82-88$ male and $83-88$ female required by this lowering, (e) extension of death rates to age $120,(f)$ consideration of the changes during recent years in the ratio of male to female death rates. The tables here proposed are called the 1950 tables. There are no changes from the 1949 tables in death rate at ages $30-81$ male or 20-82 female. The proposed death rates are shown in Table A, and various comparisons with other mortality tables in Tables B, C and D. The ratio of male to female mortality at age 10 is $158 \%$ instead of $253 \%$, which seems to have been an erroneous extrapolation.

In Table E there is shown a comparison of the new death rates with those of the 1949 tables. The principal changes from the annuity viewpoint are at ages 90 and beyond. In preparing annuity mortality tables it would seem an axiom that no such death rate should be higher than either (a) population or (b) insured life death rates for the same age and period of time. The comparative figures shown in Table F indicate that at ages above 95 the Jenkins-I ew 1949 tables violate this axiom. In view of the magnitude of their achievement, it is with reluctance that one recommends any changes. But the extension to age zero is a necessity. And the lowering of death rates at the older ages seems also a necessity due to (a) the fact that such a change is conservative in the case of annuitants, (b) the impact of both population and insured life material and (c) the fact that the old ages are to be much more important in the future than they have been in the past.

The volume of intercompany annuity data was scanty at both these extremes of the life span. The population data, duly projected into the future and modified for class selection, make a firmer basis than an extrapolation from annuity data alone. Where annuity data fail, we use population figures, and where these run out (age 109), we use a carefully prepared extension of insured life experience-the British A1924-29 table.

TABLE A
Annuity Mortality, 1950 Table
Death Rates per 1,000

[^0]A "model-office" comparison of reserves for immediate single life annuities without refund on the lives of men and women together shows the following relationships: The 1950 table was $6 / 10$ of $1 \%$ higher than the 1949 table (unmodified); equal to the 1937 Standard; $3 \frac{1}{2} \%$ lower than the 1937 Standard set back 1 year in age; and 7\% lower than that table set back 2 years in age. As many companies are now using the one-year setback, the use of the 1950 table would actually decrease the total of immediate annuity reserves to be held by such companies. These results are

$\dagger$ Not given.
largely due to the fact that at the important annuity ages 85-95 the 1937 table has rather low death rates, especially on female lives.

In Table G are shown typical annuity values on the 1950 table at $2 \frac{1}{2} \%$ interest and a comparison with the 1949 table and also with the 1937 Standard. It hardly seems desirable to publish the commutation columns until there is general agreement as to the death rates.

Although the above might seem to complete the task in hand, there are a number of most interesting things which we have observed during the course of this work. Some of these will now be set forth as intriguing byproducts of the main object of endeavor. These will include also the reasoning behind the proposed changes.

## MORTALITY DIFFERENTIAL BY SEX

Until 1928 it was the custom to prepare annuity mortality tables separately for each sex, as also population tables of mortality. Then James D. Craig presented ( $T A S A$ XXIX, 123) what later came to be called the Combined Annuity table. It was for male lives, but was used for female lives by taking an age four years lower. This convenient principle was quickly seized upon by other actuaries and applied to other annuity
tables. In May 1938 the Standard Annuity Table had a five year differential. In all of these tables, however, it was recognized that the rule would not apply in the first few years of life. Separate extensions were presented later for the ages below ten.

A survey of this matter may be obtained in Table B, showing ratios percent of male to female death rates at representative ages throughout

REMARKS: The J-L 1949 death rates at ages 100 and over, for each sex, violate the rules by being higher than both (a) population and (b) insured life death rates. Also note that this is true even though $(a)$ and $(b)$ are for much earlier years of experience. If allowance is made for this factor, then age 95 would probably come under the same ban. Higher J-L death rates are indicated by italics or bold type.

* Not given.
life. Here there are two population tables for white lives in the United States (1939-41 and 1947); the 1937 Standard Annuity basis; two by Jenkins and Lew (1943 and 1949); and finally the 1950 basis (Table A above). In passing, it may be mentioned that the 1959 and 1979 tables had the same sex differentials as the 1949 table. Probably very few actuaries or biostatisticians have observed the marked differences in recent mortality, when set forth for each sex. As will appear in the charts below, these differentials have been increasing every decade for at least thirty years. The changes during the seven years from 1940 to 1947 have been
especially extensive. The peak at ages 15 and 20 has come into being along with the widespread use of the motor vehicle. Perhaps the boys were playing in the streets while their sisters were indoors or in the yard near to the home. The second and less high peak appears at ages 50 to 60 , when heart diseases have their toll, or more accurately the cardio-vascular-renal diseases. Ever since 1920 this peak has been increasing in

size. Also it has moved from age 60 to 50 . A more detailed and extended review of these phenomena appears below.

By contrast to the population tables the 1937 Standard Annuity data seem artificial and at certain ages quite out of line, namely, ages $10-20$, $50-60$ and $90-108$. At age 15 this table shows equal death rates for both sexes as against an $80 \%$ excess for males in other tables; at age 108 it has
a $70 \%$ excess for males as against relative equality in other tables. At certain other ages also it is quite unrealistic. The annuity tables have sharper peaks at ages $50-60$ than do the population tables, and even reach $210 \%$ as ratio of death rates of men to those of women. If these facts have not been brought to attention in the literature of either mortality or sex, it is because they are of relatively recent occurrence. There is nothing very startling in the ratios for $1900-02$, where the maximum ratio, $121 \%$, is for the first year of life, and the next highest is $115 \%$ at age 50 .

A friend of mine, who is head of the astronomy department of a great university, upon seeing the figures of Table $B$, reacted like the farmer who saw a giraffe for the first time, saying, "I just don't believe it!" The question is: How can the numbers of men and women be approximately equal in the population, when the former have $30 \%$ and $40 \%$ higher mortality than the latter? This question may be answered by considering a somewhat typical situation. In a normal year there are 1,056 boys born to every 1,000 girls. In a recent mortality table it is not until age 50 that the female population has gained equality in numbers. Assuming a male death rate of two per 1,000 for 40 years, divide this by 1.30 to obtain 1.54 per 1,000 as the female death rate. At age 40 there are 1,056 times .92304 or 974.73 men and 940.22 women. This gives a $3.7 \%$ excess of men. For the next 50 years of life, assume a yearly death rate of 15 per 1,000 for men and (dividing by 1.40 ) of 10.714 per 1,000 for women. Thus for a unit starting at age 40 we have at age $90, .46969$ men and .58357 women, a ratio ( $\mathrm{F} / \mathrm{M}$ ) of 1.2424 . This is $19.8 \%$ greater than 1.037 , and thus at age 90 we would expect $19.8 \%$ excess of women. Hence, if at age zero there is a $5.6 \%$ excess of males, at age 40 a $3.7 \%$ excess of males, equal numbers at age 50 , and a $19.8 \%$ excess of women at age 90 , then the actual population figures as a whole are not so inconsistent with these hypotheses. It is because of (a) the excess of male births and (b) the extremely low death rates, that these figures stand as representative and consistent.

The U.S. population in April 1950, at the decennial census, is expected to be about 1,008 females to 1,000 males as against a corresponding figure of 994 in 1940. As this is the first U.S. census with such an excess, the above discussion is doubly appropriate at this time.

The matter of "secular trend" in mortality has assumed considerable importance in recent decades, due partly to the fact that death rates have decreased proportionately so much more at the younger ages and so very little at the oldest ages. When we consider the ratios of male to female mortality, there has also been a remarkable "secular trend." During the last 45 years the principal increases in the $M / F$ ratio of death rates have
been at ages 5 to 70 . They have ranged from $30 \%$ to $75 \%$, averaging at these ages, $48 \%$. Thus these ratios have increased at the very ages where death rates themselves have declined. The females have benefited more than the males.

These figures have paralleled five events in particular: (1) a vast decline in deaths from tuberculosis and the infectious and parasitic diseases, (2) an increased urbanization of the people, (3) a continued decrease in the size of the family, (4) a marked increase in the use of machinery in commerce, industry and the home and (5) freer dress and more athletic life of women. The decrease in the size of families has run parallel with the increase in urbanization. It is mentioned here because tuberculosis, for example, has so often been related to childbirth and matters incident thereto. The substitution of mechanical developments in place of manual labor would be expected to decrease heart diseases, but they have increased relatively, due to the decline in so many other causes of death. The transformation has probably been more complete in the home than in either office, factory, mine or transportation. The washing machine, vacuum cleaner, waxer, sewing machine and several other conveniences have replaced many fatiguing and often "back-breaking" jobs of a generation earlier. Women have perhaps adapted themselves better than have men to the atomization, rationalization and artificialities of modern life. The disappearance of the whalebone corsets and the appearance of women in light athletics have no doubt had an influence favorable to the longevity of women. These are among the many changes which have taken place during the first half of the twentieth century, now under brief review.

In a distinguished book, Exercise and Heallh, Dr. Woods Hutchinson has used the key phrase, "Muscle makes the man." And able biologists have pointed out that the muscular system is in general of greater moment to men than to women. Thus as machinery takes over more and more of the operations which people used to do, it may be that the men have been affected the most. The shorter hours of work in recent years have been an endeavor to remedy the situation. But so often the sedentary occupation is supplemented by sedentary recreations-watching the other people play ( 100,000 watching a few score at play), sitting at the movies, the radio and now the two combined in the television set, sitting in the automobile as it rolls along! These have so often become our recreations rather than doing things ourselves. We so often buy what the Young Men's Christian Association calls "canned amusements," rather than coordinating brain and hand in some form of play or work which is more personal and instinctive, and therefore creative. This is the problem of the adult education movement in our cities and suburbs, and it is also the
problem of every citizen. Benjamin Franklin two centuries ago summed it up in a single sentence: "Dost thou love life-then make the most of the minutes, for life is made up of minutes!"

Of course, the slogan of the city has no relation to muscles and often seems to depart from the ancient ideal, "healthy mind in healthy body." It is to develop the forebrain, which most distinguishes man from the animals. This is a task to which many are called, but few are chosen. Those who have permanently fallen by the wayside in one direction or another are so many, that one can appreciate Arnold Toynbee's view ( $A$ Study of History) that our so-called civilization is already on the decline, like that of ancient Rome and so many others of past centuries.

The remarkable data which have come to attention regarding mortality differentials by sex would warrant a paper by themselves. In fact, one was published in the April 1938 Milbank Memorial Fund Quarterly, "Sex Differences in Mortality in the United States" by Miss Dorothy G. Wiehl (vol. 16, pp. 145-155). The events of the succeeding twelve years make it desirable that a sequel to that work be published at an early date. She showed data for England, Canada and New Zealand, as well as for the United States, and it would be of interest to see similar material for other lands and at various decades of experience. In India, for example, and in some of the Latin countries the facts may be very different. If so, it would throw light on causation.

Such material as has come to my attention would lead to the following tentative inferences, now set down for the record:

1. Urban life today in the United States is generally relatively harder on men than on women (exceptions, yes).
2. White men are relatively better off in the Northern States, next best in the Southern States and worst in the Western States-as compared with the corresponding white women's death rates.
3. Canadian men make out relatively better than men in the Northern States of the U.S.A. At ages 10 to 60 the difference is about $10 \%$ in the M/F ratio; at other ages, not much difference. But, compared with the M/F ratios for the entire U.S.A. (whites) the Canadian ratios are lower at ages $10-70$ by an average of $30 \%$.
4. English ratios M/F are higher than those of the U.S.A. at ages over 50 ; at younger ages they are definitely lower. The first of these facts may be due to the greater urbanization in England; the second fact, to the larger share of deaths from accidents and violence in the U.S.A.
5. Negro ratios $M / F$ are lower than those of whites at ages 5 to 70 and the reverse at older ages. At each group of ages the difference is about $15 \%$.
6. The Canadian results above accord with the more rural character of Canada, and the British data with the greater degree of urbanization there. These both are in harmony with the fact that the U.S.A. used to be more rural than it is now.
7. The excess mortality of foreign-born people (in the U.S.A.) may be considered, especially as they have more often been men than women. But the proportion of foreign-born has been decreasing in those very

## CHART I

Percentage Excess of Male Death Rate over Female, U.S. Wertes, for Years Stated

years, when the spread between mortality of men and women has been increasing. Furthermore, the death rates of foreign-born do not now differ nearly so much as formerly from those of native Americans (see Length of Life by Dublin, Lotka and Spiegelman, 1949 edition, pp. 5558 ). Thus this factor can be of only minor significance; and more especially so since similar differentials have been found in other Anglo-Saxon countries which have not had the infusion of foreign-born migrants.
8. In making these comparisons, one feels safer with tables which have

## CHART II

Percentage Excess of Male Death Rate over Female, Intercompany, Annuitants

not been forced into the Makeham mold. In general, the population tables have not been so forced or distorted.
9. Many sociological forces are at work which should lead these M/F ratios to level off after a while. One is reminded of an extreme analogy in a section about Russian men and women in Ellsworth Huntington's great work, Mainsprings of Civilization (1945), pages 410-415. During the long, cold winters the women kept busy caring for the children and livestock, cooking and other household duties. These kept them in condition. But the long continued idleness of the men led them to fall into dissipation and

CHART III
Percentage Excess of Male Death Rate over Female, Foreign, for Years Stated

personal dissolution. For these reasons Russian locomotive engineers were usually women-they were more reliable! In recent decades the Russian climate has been much warmer, and the men have been working in factories during the winter months. Thus the vicious circle has been broken!

Charts I to IV show the relative death rates throughout life for the

## CHART IV

## Percentage Excess of Male Death Rate over Female Miscellaneous Tables

a a Metropolitan Life Industrial 1st 9 months 1949 (whites)
b b Canadian Government Annuities 1944-1948
respective sexes. The ratio of male to female death rate as an excess over $100 \%$ is the indicated quantity. There are four charts-one for United States population data, one for Canadians, British and New Zealanders, and a third for annuitants, while a fourth shows miscellaneous recent data. The visual appeal of the charts is more impressive than the rows of figures, such as those in Table B. There are also certain additional tables included in charts, so that the evolutionary aspect stands out more clearly. The death rates for each sex are shown numerically in Tables C and D.

## 1937 STANDARD ANNUITY TABLE

The 1937 Standard Annuity table is evidently outmoded in two particulars at least: (1) Its ratios of male to female death rates are at many ages at wide variance from those of (a) the general population and (b) annuitants. Thus I would agree with Messrs. Jenkins and Lew that the 5 year setback in age is not close enough to realities, and must (reluctantly) be discarded for future tables of annuity mortality. (2) At ages 1 to 40 its death rates are higher than those of the U.S. 1946 tables, and this should not occur in an up-to-date annuity table. Jt seems axiomatic that annuity death rates should not be higher than either (a) population or (b) insured life death rates for comparable years of experience.

## CENTENARIANS

Question may be raised as to the use of age 120 as the final age in the proposed (1950) mortality table (age 121 as omega, the age not reached). This goes back to 1934, when British actuaries produced the A1924-29 table. This is the most recent such table at these ages. The literature was reviewed in the paper "Centenarians" in September 1939 (TASA XL, 372-378). For convenience of the present reader, some extracts and brief simplifications will now be presented:
(1) The trend in recent years has been rather steadily toward a higher limiting age in mortality tables. McClintock (1898) had 109; the Standard (1938) female had 115 and the British A1924-29 had 121 as its limiting age (as shown on p. xxix of the introduction to the monetary tables). In the case of insurance policies the Company may pay the face amount when a certain age is reached (as 96 in American Experience and 100 in CSO Table). Thus there is no mix-up or embarrassment when anyone lives beyond the "limiting age." But in annuity matters the situation is different. If the terminal age is 107 (as in American Annuitants female table) and someone lives to 109 , what reserve is to be held? The conservative procedure is to determine the oldest (authenticated) age that anyone has lived, and then extend the annuity table a few years beyond that age.
(2) The oldest authenticated age in the "Centenarians" paper was 113.

The use of 120 as arbitrary final age would seem adequate and appropriate for annuitants, though one may feel that no one ever has lived or ever will live beyond age 115. Since the 1939 paper was published I have found another case of age 113, a woman in central N.Y. State who apparently lived a few weeks longer than the French Canadian man mentioned in the paper.
(3) There are three alternative ways of deriving columns of $l_{x}$ and $d_{x}$ (see p. 375 of 1939 paper). The best way is to use decimals rather than only integers. The preferred method was used in Spurgeon's textbook and also in the A1924-29 table and in the Jenkins-Lew paper. The method used in the American Experience and CSO tables and in the 1937 Standard Annuity table is definitely outmoded, especially for annuitants.
(4) It is not necessary to reach eventually a death rate of unity (examples on p. 376 include U.S. 1939-41 table). The rationale seems to be, if you are in doubt as to the limiting age, don't show any! Leave the matter open for future research!
(5) The optimistic school believes that human life can attain to such ages as 150 and 200 years. The example of C. J. Drakenberg is cited (145 years, 325 days) and Prof. Steffensen said "The principal facts of his life have, as far as I know, never been disputed" (JIA LXII, 103). Perhaps father and son had the same name and the date of birth of the father was associated with the date of death of the son! These dates were 1626 and 1772, long before modern methods of vital statistics were adopted!

The pessimistic school believes that 106 or 107 years is the longest period of human life in the past (based on life annuity experience in insurance companies) and that "history repeats itself" here as elsewhere.

The use of 121 is between these extremes-an endeavor to walk on the middle path of safety and conservatism!

## AgES ZERO AND ONE

In the 1937 Standard Annuity table the death rates at age zero were 11.31 (male) and 9.01 (female). These were $90 \%$ of the rates by policies for intercompany juvenile ordinary issues of 1925-1934, after adjustment for sex. The ratio of male to female death rates was made the same as in the U.S. 1929-1931 Life Tables for white lives, namely, $126 \%$ (TASA XL, 77-87). Fifteen years have elapsed since the latest year included in this experience. Thus it must be regarded as outdated, provided that anything more recent can be found. In October 1948 (TASA XLIX, 437442) mortality experience at ages zero and one on insured lives was presented from each of several companies. These were for all or some of the years 1940-1946. The death rate at age zero was about 4 per 1,000, and
that for age one was about 1.65 per 1,000 . This includes approximately $40 \%$ girls and $60 \%$ boys, there being a $20 \%$ differential in mortality by sex. These data were confirmed by unpublished material from another large company. The proposed death rates for the 1950 annuity table have been obtained by using $90 \%$ of these insured life death rates (1940-1946), modifying the male figures so as to have $\mathrm{M} / \mathrm{F}$ ratio of $126 \%$ at age zero and $116 \%$ at age one. This procedure gives the rates shown in Table A at these two ages, namely:

DEATH RATES PER 1,000

| Age | Male | Female | M/F |
| :---: | :---: | :---: | :---: |
| 0 | 4.04 | 3.21 | $126 \%$ |
| 1 | 1.58 | 1.36 | 116 |

These conform to the rule that annuity death rates should never exceed insured life figures for the same sex, age and period of exposure. The male death rate at age zero is about one-fifth of that in the CSO underlying experience table and one-ninth of that of U.S. whites in 1947. The female death rate at age zero bears a similar relation to the U.S. 1947 female table. In each case the ratio to the 1937 Standard Annuity table (age 0) is about one-third.

At age one the male death rate (1.58) is about one-third of that in the CSO underlying experience and in the 1937 Standard table; while it is two-thirds of the 1947 figure. The female death rate (1.36) is a somewhat smaller proportion of the corresponding female tables. These facts are in accordance with the secular trend as to mortality and sex.

Incidentally, the death rates at age one are about two-fifths of those at age zero, instead of one-half as in the 1937 Standard table, one-fourth in CSO underlying experience and one-ninth in several recent population tables. This may be defended on the grounds of class-selection as well as of the secular trend.

If the female death rates were to be modified, instead of the male as above, the death rates at age zero would be $5 \%$ less and those at age one the same as above. The figures for males would be 3.86 and for females 3.06 at age zero. There is very little annuity business at these early ages, and the necessary choice of death rates may seem somewhat academic. This is particularly so, because a return of premium death benefit often accompanies deferred annuities, especially at young ages. The issuance of an immediate annuity without return is probably very rare in these first two years of life-but there are some.

## AGES TWO TO TWENTY-FIVE

The female death rates of the 1949 table were modified at ages 11-19, so as to permit a reasonable extension below age 10. At ages 2 to 9 the female death rates were obtained from a projection of U.S. 1939-41 and U.S. 1947 tables, arranged so that the figure at age ten is the same as in the 1949 table. The male death rates were obtained by multiplying by the $\mathrm{M} / \mathrm{F}$ ratios at these ages. These ratios were lowered so as to be $158 \%$ at age ten instead of $253 \%$. The $\mathrm{M} / \mathrm{F}$ ratio in the U.S. 1946 (white) table is $154 \%$. Other $\mathrm{M} / \mathrm{F}$ ratios at these juvenile ages were obtained by interpolation.

## AGES 86 AND OVER

At ages 86-94 I have used the "curve of sines" ( $T A S A$ XXXIV, 9) to merge the 1949 female death rates with those derived from the U.S. 1939-41 and U.S. 1946 tables projected into the future. The projection at these ages was prepared by deducting $20 \%$ from the U.S. $1939-41$ death rates and multiplying the results by the respective ratios of J-L 1949 to J-L 1943 death rates.

At age 90 this result was 173.44 , quite close to the 1949 female death rate of 176.16. At ages $86-90$ the 1949 table had the greater influence, and at ages 91-94 the population projection had the larger weight upon the merged results. At ages 95-109 a similar use was made of the U.S. 1939-41 female white table. The percentage deductions graded down from $18 \%$ at age 95 to $6 \%$ at age 109. In each case the net death rate was further reduced in the ratio of J-L 1949 to J-L 1943 death rates.

For ages $110-120$ a merger was made into the insured life tables of England, A1924-29. This is the most recent available at these ages. At age 109 the ratio of female death rate to this table was .771 and at ages $118-120$ it was taken as unity. The intermediate death rates (ages $110-$ 117) were inserted by interpolation in these ratios. (1.000-. $771=.229$ and $.229 \div 9=.0254$.)

After the female death rates had been thus obtained, the male rates were derived by multiplying by the respective $M / F$ ratios. The latter were as derived by Jenkins and Lew, but modified so as to be never less than $100 \%$. At ages 107-120 the male and female death rates are nearly equal to each other.

## GRADUATION

Before the resulting mortality tables could be offered for general use, they had to be subjected to a fourth-difference smoothing process near the extremities by Robert Henderson's formula A, with $n=a=1, k=e=$ $1 / 3$ and $z=2$. At ages $1-19$ after grading the male table, we graded the ratio $M / F$ rather than the female rates. The graded female rates were
obtained by dividing the graded male rates by these graded $\mathrm{M} / \mathrm{F}$ ratios. The same procedure was followed at ages $80-120$. In order to secure greater smoothness at these older ages, use was made of the sixth-difference formula A with $n=a=3, k=e=.009$ and $z=3$. This gave excellent results.

## SETTLEMENT OPTIONS-PAYEE OPTION DIFFERENTIAL

There is at present considerable difference in practice among the companies as to how rates for settlement options differ from those for new annuities. Furthermore, a few companies make use of a different rate when

TABLE H
Deaths (Payee Selection and All Others)

|  | Actual | Expected | Ratio |
| :---: | :---: | :---: | :---: |
| Female | 3,607 | 3,403 | 106\% |
| Male. | 964 | 1,015 | 95 |
| Total. | 4,571 | 4,418 | 103\% |

TABLE I

|  | Deaths (Payez Selection) |  |  | Deaths (Selection by Non-payee and Unknown) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Actual | Expected | Ratio | Actual | Expected | Ratio |
| Female. <br> Male. | 1,010 631 | 1,068 | $95 \%$ 94 | $\begin{array}{r} 2,597 \\ 333 \end{array}$ | 2,335 340 | $\begin{gathered} 111 \% \\ 98 \end{gathered}$ |
| Total. | 1,641 | 1,743 | 95\% | 2,930 | 2,675 | 109\% |

the selection is made by the payee than by someone else. Most companies make no such differential charge.

The latest mortality experience under settlement options (Table 25 in paper by Jenkins and Lew) shows on male lives a $5 \%$ lower mortality than for immediate annuities, while for female lives it is $6 \%$ the other way (higher). This includes all options, both by payee and by others. The figures are shown in Table H, where the "expected" mortality is that of nonrefund immediate annuities. When the picture is thus viewed as a whole, it is evident that settlement option mortality is not far different from that of immediate annuities. Table I shows the figures for (a) payee selection and (b) all others.

Here is evidence of a $14 \%$ differential in mortality as to payee selection, but it is chiefly on female lives ( $16 \%$ against $4 \%$ for males). Only one-fourth of the payees are male. It is interesting to observe, as to the deaths, that males form $40 \%$ of those with payee selection, but only $11 \%$ of the others.

In the book Settlement Options by Flitcraft and Company one finds that seven companies make an age differential as to the payee option. These companies are about equally divided as to the manner in which this is done. There are four which word their contracts so that a benefit is given where the election is made by the insured and recorded during his lifetime. The other three penalize the election of option by the payee. The former method has the advantage of being diplomatic and positive. Under the former method, the policy provides that if the life income option is elected during the insured's lifetime, the age used will be —_- years older than the true age of the payee (the number of years of differential is one, two and three among the seven companies). The other method provides that the age is set back —_ years if the sum applied under the option is the cash value or endowment maturity value, or any part thereof. In such case the beneficiary receives less than the value printed in the table opposite her age, and the effect is negative and not so pleasing. Of the seven companies, there are two with one year differential in age, two with two years and three with three years. The average number is 2.1 , and when weighted by assets, 1.6.

The last bit of information is doubly interesting, because a $14 \%$ differential in mortality corresponds to about $1 \frac{1}{2}$ years in age, and the use of two years in the contract is a conservative practice to correspond to this fact of experience.

The percentage adjustment in mortality which is equivalent to a oneyear setback in age has been referred to several times in the Transactions ( $T A S A$ XL, 243 and XLI, 229). The ratio has usually been closely related to the value of $c$ in the formula of graduation. (Gompertz or Makeham's 1st or 2d law). Thus in the 1937 Standard Annuity Table, $c=1.079$, and the death rate increases by nearly $7.9 \%$ at each age. (TASA XI, 244.) In the 1949 Annuity Table (Jenkins \& Lew) the value of $c$ is 1.104 for males and 1.120 for females. Thus one would look for approximately a $10 \%$ yearly increase in mortality for males and $12 \%$ for females. The actual rates of increase were as follows (Table J), as may be seen by simply dividing one death rate by its predecessor in the ultimate mortality table.

It will be observed from Table $I$ that at the principal annuity ages the yearly increase in death rate is a little less than would have occurred if the tables had followed the Gompertz formulas.

## $\mathrm{LO}_{10} C$

"Gompertz's law may be stated as follows: The vital force or recuperative power of each individual loses equal proportions in equal times; and the proportion of vital force so lost by each is universally the same, being approximately represented by $\log _{10}=.04$ " (W. M. Makeham in 1890) see JIA XXVIII, 320. As an amendment to this "universal" law we read the following written fifty years later: "There is a tendency for the value

TABLE J
Rate of Increase in Death Rate

| Ace | 1949 Table |  | 1950 Table Where Different |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Male | Female | Male | Female |
| 10 | $2 \%$ | $9 \%$ | 3\% | 1\% |

of $c$ to decrease with the progressive decline in mortality, which has been so marked during recent decades" (TASA XLI, 229). This latter remark appeared in a report on annuity mortality by the Joint Committee. It was based chiefly upon observation of experiences prepared in the United States, such as American Experience in 1868 (.046), Thirty American Offices in 1881 (.041), Canadian Men in 1918 (.040), American Men in 1918 (.034), American Annuitants in 1920 (.035), Combined Annuity in 1928 (.035) and the Standard Annuity in 1938 (.033). It may be observed that the first of these values was about $40 \%$ higher than the last listed and the progression was rather steadily downward. The comment of the Joint

Committee came a year prior to publication of The Commissioners' Standard Ordinary Table (.039), which tended to reverse the trend by use of a higher value of $\log _{10} c$. The rate of disability in the Inter-Company report of 1926 had a grading formula with $\log { }_{10} c=.034$, the same as in the $\mathrm{AM}^{(6)}$ table with which it was combined.

When British tables are reviewed, there are some evidences of a parallel tendency. The Actuaries' table in 1843 and the Healthy Males in 1869, both used . 040 ; the British Offices Assurances in 1893 used .039 and the corresponding Annuities . 038 ; the A1924-29 insurance tables in 1934 were not Makehamized, but a value of .035 seems to best fit the picture. When we come to the British annuitants of the years 1900-1920 a more complex pattern presents itself, involving both higher and lower values of $\log { }_{10} c$. In the Government Annuities we find for males .052 based on ages 44-70 and .040 based on ages $64-89$, while for females the value is .046 at both sets of ages. The Company male annuities, $a^{(m)}$, used . 034 at ages $50-70$ and .035 at ages 81 and over in two Gompertz formulas. The corresponding female table, $a^{(f)}$, had two Makeham formulas which overlapped, ages $40-$ 85.053 and ages $80-104.030$. Thus the highest and the lowest values so far recorded above occurred in this last experience. These two sets of British annuitant data seem to be the only tables so far, which had different values of $c$ for the respective sexes. They also went further and had two different values of $c$ for males and two others for females. This seems to overwork the Makeham hypothesis, without any advantages of simplification in joint life calculations. In these tables the values of $\log _{10} 0$ for females are both higher and lower than those for males.

Authors Jenkins and Lew have continued the difficult British custom just observed, by having different values of $\log _{10} c$ for the respective sexes. In each set of their tables the value is higher for females than for males, the difference being uniformly .006 , but they have used a single value of $c$ for each table. Instead of continuing the trend toward lower values of $\log { }_{10} c$, they have definitely reversed that trend-first, by having high values (greater in each instance than .040) and, secondly, by increasing those values as they project into the future, as 1959 and 1979. Their proposals for $\log 10 c$ are as follows:

LOG 10 (JENKINS AND LEW, NOVEMBER 1949)

|  | 1949 Tables | 1959 Tables | 1979 Tables |
| :---: | :---: | :---: | :---: |
| Men. | . 043 | . 045 | 049 |
| Women | 049 | 051 | 055 |

In these figures, we may observe an increase of .002 for each ten years of advance into the future. The figure of .055 for women in 1979 is higher than any previously recorded value, so far as I have observed, although not much higher than the $a^{(\prime)}$ figure (.053) at ages $40-85$ produced in 1923 in England.

As W. P. Elderton and A. E. King showed in 1910 (JIA XLIV, 293301), and V. Howell in 1920 (TASA XXI, 178-206), it is usually better to determine a value of $\log c$, and use the table as though it were Makehamized for joint life calculations. This gives better results than to force the data into a Makeham mold. The values of $\log c$ to use in the 1950 tables are the same as in the 1949 tables, .043 for males and.$c 49$ for females.

One further remark may be made as to the value of $\log c$. The death rate at or about age ten is nowadays not very far from zero. It is a fraction of unity per 1,000 . Thus the function of $c$ is to advance the death rate through most of the range from zero to unity. This it does by more or less equal geometric intervals. If the last age in a table is 95 , as in the American Experience table, one would expect a high value of $\log c$. There are only 85 years during which it can have its effect. But if the final age is 120 , the value of $\log c$ would be expected to be lower, as there is a further quar-ter-century in its path. A logical extension of this thought would be that when the calculated value of $\log c$ is much above .040 , then the final age is lower than it should be. But this thought should wait upon experimental verification. If it were to prove true, it would be a splendid vindication of foresight and penetrating observation by Messrs. Gompertz and Makeham.

A number of writers have expressed the opinion that Makeham's first law can hardly be expected to hold at other ages than 30 to 80 . Thus to follow Vaihinger's doctrine of "as if" for all ages, in setting up a table of uniform seniority (addition to younger age to obtain equal ages), requires experimental verification. One has to balance the great convenience of the method against the degree of fidelity to the original data.
