# IV <br> Analysis of High-Cost Cases 

## A. Background

The data we reviewed indicate that, while only $1 \%$ of claimants have expenditures above $\$ 25,000$ in any given year, these individuals account for more than $25 \%$ of claim costs. Thus, any analysis of risk assessment and risk adjustment must pay special attention to these large claims. If the goal of risk adjustment in the public policy sense is to motivate carriers to be efficient, as opposed to motivating carriers to select the best risks, then finding a solution to the problem of compensating carriers fairly for these high-cost claimants is an absolute necessity.

Reinsurance is one traditional method for dealing with these high-cost claims. But the incentives it generates may create perverse incentives. Generally, a reinsurance system for risk adjustment would need to be mandatory for all participating carriers. The reinsurance premium would then be derived from the expected cost of all the high-cost claims within the system. If efficient managed care organizations as well as inefficient indemnity carriers are participating, the more efficient carriers end up subsidizing the inefficient ones through the reinsurance premium since payment is based on actual claim dollars paid, and the less efficient carriers are in effect rewarded for their higher claims. More efficient health plans also have fewer cases which exceed the reinsurance limits. Thus, this system does not reward better management of care.

The alternative that has perhaps received the most attention is that exemplified by the New York highcost condition and California HIPC methods. Instead of paying carriers for high-cost cases on the basis of actual claims, payments are based on the occurrence of specific high-cost diagnoses or procedures and fixed in advance. Thus a plan with an enrollee who is diagnosed with myeloid leukemia might receive a predetermined payment of, say, $\$ 120,000$. Since the payment is known in advance to the carrier, the carrier's incentive is to provide efficient care. At the same time, if the
plan knows that it will be compensated for having a disproportionate number of high-cost enrollees, its incentives for risk selection, and the consequences of adverse selection, are reduced.
None of the methods we have tested so far pay particular attention to the prediction of expenditures for high-cost cases. Although some DCG models make a distinction for inpatient diagnoses, and should thus capture most high-cost cases, they aggregate together many clinically distinct diagnoses that may have somewhat different expenditures on average. Additionally, the analyses described in Chapter III are all based on data truncated at $\$ 25,000$, essentially assuming some form of reinsurance system for claims above that amount. We sought to investigate alternative methods for assessing the risk of these high-cost cases.

We explored the potential of a method focused on high-cost conditions to improve on age and sex and the ADG models. Since many higher-cost hospitalizations were modeled explicitly under the DCG method, we did not explore the addition of our conditions to these models. Instead, we evaluated our results in relation to the PIPDCG and EDCGDX models.

The large amount of data available to us for this study provided an opportunity for a new analysis of high-cost diagnoses. We followed the approach that the HIPC took in developing its list of marker diagnoses, as described in Chapter II (HIPC, 1995). The HIPC list includes groupings of diagnoses that, when associated with a hospitalization, tend to generate costs in excess of $\$ 15,000$, and that also meet various clinical criteria: (1) the assignment of the diagnosis must be relatively nondiscretionary; (2) the decision to hospitalize must also be relatively nondiscretionary; (3) careful ambulatory management will not necessarily be sufficient to prevent hospitalization; and (4) the condition must have some degree of chronicity to it, so that a plan could select against individuals with that diagnosis. The lists of diagnoses and procedures that New York State and Kentucky use in their high-cost risk adjustment mechanisms
are quite short (the New York list accounts for less than $5 \%$ of expenditures over $\$ 25,000$ ) and research is currently under way to extend them. Thus a list comparable to the HIPC list seemed more likely to indicate the potential of a high-cost condition-based method.

We initially considered the use of the HIPC list itself in testing a high-cost condition approach. Due to the more limited amount of data available to the HIPC, however, certain high-cost diagnoses (several types of cancer, in particular) did not emerge as HIPC marker diagnoses. We constructed an alternative list, based on our own data. We relied on our clinical consultant's judgment to approximate the diagnosis screening process that the HIPC undertook. We also compared our list with the HIPC diagnoses to confirm our selections.

## B. Methods: Development of an Alternative List of High-Cost Diagnoses

## 1. Initial List of Diagnoses

We identified high-cost diagnoses using a combined data set from pools representing approximately $80 \%$ of all observations eventually used in the study, or more than 3 million records. Since our initial analysis showed that $95 \%$ of all enrollees with expenditures over $\$ 25,000$ had one or more hospital admissions, we only used data for enrollees with an inpatient episode in a year to develop our list.' Unlike in the HIPC process, we were unable to use secondary inpatient diagnoses, because these were not recorded in our data.
We first summarized statistically total expenditures per enrollee for all inpatient diagnoses. To simplify the analysis, we did this separately at the three-, four-, and five-digit level of coding. ${ }^{2}$ Beginning with the fourdigit list, we then identified diagnoses which met the following conditions:

- A four-digit diagnosis code had to appear at least 10 times in our data as the only principal inpatient diagnosis; individuals with more than one principal inpatient diagnosis (thus necessarily more than one hospitalization) were not used for development of the list. ${ }^{3}$
- Mean expenditures for these occurrences had to be $\$ 25,000$ or above.
- Assignment of the diagnosis and the decision to hospitalize are relatively nondiscretionary.
- For this diagnosis, hospitalizations cannot always be prevented through proper medical management.
- The condition is one that plans could conceivably select against.
To be specific, our clinician assigned a score of 1 to 3 indicating how discretionary assignment of the diagnosis and hospitalization are, how preventable hospitalizations are, and how likely it is that a plan could systematically avoid enrollees with the condition. In each case, a lower score indicated lower discretion or potential for gaming. Any diagnosis with a score of 3 on any dimension was excluded, and any diagnosis with more than one score of 2 was also excluded. We did not exclude any cancers.

The above procedure was applied to all four-digit codes for which mean expenditures were above $\$ 25,000$ and which showed a frequency of 10 or above in our combined data set. We also considered whether any five-digit codes should be broken out. Because not all insurers record ICD9 codes at the five-digit level, and because we wanted to avoid making the list unduly complex, we decided to set a higher threshold of frequency for five-digit codes, requiring that they occur at least 50 times in the data. We then included a specific five-digit code in the list only if:

- It represented an acceptable condition according to the same criteria as applied to the four-digit codes
- Its distribution was significantly different from the distribution of expenditures for the corresponding four-digit code.
In addition, initial episodes of care were excluded. These criteria turned out to be stringent enough that only one five-digit code was added to the list, 51881, respiratory failure. Finally, we added three-digit codes with frequencies of 10 or above and mean costs above $\$ 25,000$ that were not excluded by our criteria and that appeared on the HIPC list.

## 2. Grouping and Elimination of Diagnosis Codes

Codes were then grouped according to clinical relatedness and relative homogeneity of cost distributions. In order to increase the likelihood that the final groups truly represent high-cost conditions, groups were kept on the list under either one of two sets of conditions: (1) the code(s) in the group met the clinical criteria indicated above, and the group appeared on the list developed by HIPC; or (2) the group had a total of 50 or more cases, or, failing that, a median cost greater than $\$ 50,000$. Thus we interpreted appearance of the
group on the California list as confirmation of our clinical analysis, and indication that the condition probably was of greater significance generally than our sample may have suggested. Clinically isolated diagnoses of low frequency or generally lower cost that met our clinical criteria but were not identified on the California list were not kept on the list.
Table 23 shows the 43 groups that were obtained in this way, together with statistics describing the distribution of expenditures for each diagnosis code included. As shown, the list encompasses 52 three-digit codes, 22 four-digit codes, and one five-digit code. ${ }^{4}$ Together these codes account for $35 \%$ of expenditures in our sample over $\$ 25,000$, or about $9 \%$ of all expenditures. Only $5 \%$ of all individuals with one or more of these conditions had two or more. Only $0.3 \%$ had three or more. Table 24 shows the percentage of total expenditures over $\$ 25,000$ each group accounts for, as well as the incidence of each group in our sample. As shown, although these conditions are costly, many are also infrequent.

## C. Methods: Evaluation of the List of Marker Diagnoses

We combined the new list of marker diagnoses with two risk assessment models evaluated previously (see Chapter III): age and sex alone, and ADGs combined with age and sex. This involved adding 43 dummy variables to each of these two models, one dummy variable for each of the conditions shown in Table 24. Individuals with no principal inpatient diagnosis in any one of the 43 groups have a 0 value for each of the 43 dummy variables. Individuals with only one or more principal inpatient diagnoses belonging to a single group have the dummy variable for that group set to one. We treated individuals with multiple principal inpatient diagnoses, belonging to two or more different groups, ${ }^{5}$ in two ways:
(1) After having ranked the groups according to their mean expenditures, we assigned each such individual to the group corresponding to the most expensive principal inpatient diagnosis.
(2) We set as many of the group dummy variables equal to one as there were principal inpatient diagnoses belonging to different groups.
For example, under the first method, an individual with one principal inpatient diagnosis of 150 (malignant neoplasm of esophagus) and another (associated with another admission during the same year) of 431 (intracerebral
hemorrhage), would be assigned to the group "Malignant neoplasm of the esophagus" because mean expenditures for persons in that group are $\$ 71,000$, higher than the $\$ 56,000$ for persons in the group "Intracerebral hemorrhage." Under the second method, the same individual would be assigned to both groups.

The first method for treating individuals with multiple principal inpatient diagnoses parallels the DCG approach of assigning individuals to their highest DCG. Relative to the second method, it may reduce incentives for any clinically unnecessary hospitalizations, and it is somewhat simpler. The second method yields higher predicted expenditures for individuals with principal inpatient diagnoses belonging to two or more groups, relative to individuals with diagnoses in only one group. Such individuals are likely to have suffered from one or more significant comorbidities during each hospital stay. Combining each of these two high-cost models with age and sex and ADGs yields four models, which we refer to as: age-sex with principal high-cost conditions (first method), age-sex with all conditions (second method), ADGs with principal high-cost condition, and ADGs with all conditions. These four models are compared to age and sex alone, ADGs alone, PIPDCGs, and EDCGDXs.
We estimated these eight models retrospectively using 1992 data for seven selected pools comprising 850,000 enrollees. To remove any systematic differences by pool, we included a dummy variable for each of the seven pools. Each coefficient for the variables describing the high-cost conditions in the model represents the average additional annual cost across all seven pools of enrollees produced by the described condition. Using the estimated coefficients, we compared the predicted expenditures with actual amounts. ${ }^{6}$ Expenditures were not truncated, since our goal was to compare the ability of different models to predict extreme expenditures.

Finally, we compared the predictive accuracy of the models for individuals as well as groups. We did this using the same measures as described in Chapter III.

## D. Results

Table 25 reports the predictive accuracy for the eight models tested; the adjusted $\mathrm{R}^{2}$ s are also compared graphically in Figure 13. The PIPDCG and EDCGDX models perform best overall, both with an adjusted $\mathrm{R}^{2}$ of 0.27 and with very similar values on other measures of predictive accuracy. The two high-cost models combined

## Analysis of High-Cost Conditions, Summary of Predictive Accuracy, Individual Results, Retrospective 1992, Data from Seven Pools, No Truncation-Adjusted $\mathbf{R}^{2}$

with ADGs perform almost identically and come quite close to that, with adjusted $\mathrm{R}^{2}$ s of about 0.24 . Age and sex alone, as expected, do very poorly, while ADGs alone reach only 0.112 . Age and sex with high-cost conditions attain $\mathrm{R}^{2} \mathrm{~s}$ of 0.16 and 0.17 .
Analyses at the group level produce essentially similar results (Table 26). As Figure 14 illustrates, in terms of mean absolute prediction error, the EDCGDX model performs best. Age and sex and ADGs alone perform worst on this measure, with PIPDCGs and all the high-cost-condition models performing similarly and
noticeably less well than EDCGDXs. On the other measures PIPDCGs perform almost as well as EDCGDXs, and better than the high-cost-condition models. Age and sex and ADGs alone always perform worst, though their relative ranking depends on the specific measure used.
Finally, for exploratory purposes, we combined our high-cost conditions with the PIPDCG model. We did this to investigate whether any of the predictive power of the conditions would supplement that from PIPDCGs. This combined model produced an adjusted

$\mathrm{R}^{2}$ of 0.321 compared with a value of 0.272 for PIPDCGs alone. Also, interestingly, with the exception of a single high-cost condition, the estimated risk weights for all conditions we developed were positive, suggesting that we had identified diagnoses of higher expected costs within each PIPDCG. These findings suggest the retrospective PIPDCG model might be
improved with the addition of some of the information provided by our high-cost list.

## E. Discussion

We found that, although they were not specifically developed as substitutes for high-cost-condition lists,
the EDCGDX and PIPDCG models perform better, in terms of predictive accuracy, than the high-cost-condition list that we developed. The performance of the PIPDCG model is particularly striking in view of the fact that it is simpler than the EDCGDX model and relies only on inpatient diagnoses. Since the PIPDCG (and EDCGDX) model we tested also includes age and sex, it can be compared directly with the age and sex with and without our list of high-cost conditions. As shown, the PIPDCG model does substantially better than age and sex with high-cost conditions, which are also based only on inpatient diagnoses.?

Taking into account the occurrence of multiple primary inpatient diagnoses improved the predictive accuracy of the high-cost list only slightly, in good part because, as described above, only $5 \%$ of the individuals with one or more high-cost conditions had two or more, and only $0.3 \%$ had three. Allowing for interactions between highcost conditions would probably then yield an even smaller payoff.

The list of diagnosis groups on which our results are based has the advantage of having been derived from a large, national data set. An extensive process of clinical evaluation, comparable to that used in development of the HIPC list, was beyond the scope of our project.

We included in our list only ICD9 diagnoses, and no procedures. In doing so, we followed the pattern set by the HIPC. This allows the method to be used prospectively as well as retrospectively. If retrospective payment is to be used, high-cost procedures such as transplants could be added to the list. Again, however, the addition of only a limited list of very high-cost nondiscretionary procedures (such as transplants, as in the current New York list) would probably contribute fairly little to the model.

The PIPDCG model is not fundamentally different from a list of high-cost conditions, except that it includes some lower cost conditions as well. ${ }^{8}$ In spite of the fact that it aggregates many high-cost conditions more than our list does, it outperforms it even when our list is combined with ADGs. This suggests that those wishing to develop a list of high-cost conditions may also benefit from a careful study of the construction of the DCG models. ${ }^{9}$ Combining this with analysis of a large data set such as ours, and an extensive clinical review such as the HIPC used, should yield a better list of high-cost conditions than any currently available.

## END NOTES

1. In addition to being relatively small in number, we did not observe any common ambulatory diagnoses for highcost individuals without an inpatient admission.
2. ICD9 codes can be recorded using three, four, or five digits. The first three digits indicate a family of clinical conditions. For example, ICD9 code 320 represents bacterial meningitis. Meningitis due to other specified bacteria (as opposed to, for example, pneumococcal meningitis, which is coded as 320.1 ) is coded as 320.8 . A more specific diagnosis of anaerobic meningitis is coded as 320.81. Many four-digit codes have no five-digit subdivisions, which may explain in part why a number of carriers only record four digits.
3. The reason we did this was to make the assignment of costs to diagnoses unambiguous. As indicated in the text, we accomplished this by summarizing expenditures at the three-, four-, and five-digit level for individuals who had only one principal inpatient diagnosis. (Such individuals could have had more than one admission as long as all admissions were coded with the same principal inpatient diagnosis.) This does not mean that we excluded individuals with multiple conditions from these high-cost analyses. We excluded them only for this step. Individuals with multiple admissions and multiple principal inpatient diagnoses were included in subsequent analyses, as described below.
4. Where a three- or four-digit diagnosis code is specified, all four- and five-digit codes below the listed code are included. For example, the three-digit code 195 includes ICD9 codes 195.00 through 195.99.
5. No individual in the data set had more than three different high-cost diagnoses.
6. To increase the number of observations for the high-cost cases in the sample, we did not use a split-half approach. Other exploratory analyses indicated that our findings are not sensitive to this decision.
7. One fundamental difference between the PIPDCG and EDCGDX models and our list of high-cost conditions is that, while our list is restricted to conditions with average expenditures greater than $\$ 25,000$, the DCG models consider diagnoses with expenditures under that amount. As a result, these models might be expected to perform better for "medium cost" diagnoses.
8. The same is not true of the EDCGDX model, which makes use of ambulatory diagnoses, and combines the information in a more complex way than either the PIPDCG model or a list of high-cost conditions.
9. In addition to the PIPDCG model, the EDCGDX model, for example, takes comorbidities into account in a manner that might be incorporated into a list of high-cost conditions.

[^0]:    *Where a three- or four-digit diagnosis code is specified, all four- and five-digit codes below the listed code are included. For example, the three-digit code 195 includes ICD9 codes 195.00 through 195.99. (Number in parentheses to right of condition is the condition i.d.)
